### **Abstract**

Consonants and vowels may play different roles during language processing, consonants being preferentially involved in lexical processing, and vowels tending to mark syntactic constituency through prosodic cues. In support of this view, artificial language learning studies have demonstrated that consonants (C) support statistical computations, while vowels (V) allow certain structural generalizations. Nevertheless, these asymmetries could be mere by-products of lower-level acoustic differences between Cs and Vs, in particular the energy they carry, and thus their relative salience. Here we address this issue and show that vowels remain the preferred targets for generalizations even when consonants are made highly salient or vowels barely audible. Participants listened to speech streams of nonsense CVCVCV words in which consonants followed a simple ABA structure. Participants failed to generalize this structure over sonorant consonants (Experiment 1), even when vowel duration was reduced to one third of that of consonants (Experiment 2). When vowels were eliminated from the stream, participants showed only a marginal evidence of generalizations (Experiment 4). In contrast, participants readily generalized the structure over barely audible vowels (Experiment 3). These results show that different roles of consonants and vowels cannot be readily reduced to acoustical and perceptual differences between these phonetic categories.

**The quest for generalizations over consonants: Asymmetries  
between consonants and vowels are not the by-product of acoustic  
differences**

Children have to acquire many different aspects of their native language. These aspects can be roughly classified in two categories, one pertaining more to learning words and their meanings, and one pertaining more to acquiring grammatical aspects of language. Of course, word learning depends at least in part on grammatical information (e.g., Gillette, Gleitman, Gleitman, & Lederer, 1999), and grammatical regularities may partly depend on lexical information (e.g., Tomasello 2000). Still, different cues in the speech signal may be used in different ways for acquiring specific parts of language. In particular, Nespor, Peña and Mehler (2003) suggested on theoretical grounds that consonants might be more relevant for lexical processing, while vowels may have a more grammatical function.

The question whether vowels and consonants have different functional roles is related to a more general issue. Traditionally, language acquisition has been thought to be possible only due to strong (probably innate) biases that shape how linguistic stimuli are processed (Chomsky, 1980). More recently, however, different authors have proposed that more general mechanisms, that operate in a variety of domains and exploit distributional regularities in their input, can account for much of language acquisition (Elman et al., 1996; McClelland et al., 1986). While functional asymmetries

between vowels and consonants are compatible with the former approach (because vowels and consonants would be intrinsically linguistic categories), one would not expect such differences if grammar were learned exclusively through general learning mechanisms – because, all else being equal, either kind of stimulus should be equally good for allowing such learning.

Experiments using artificial languages have suggested that consonants are indeed preferentially used for identifying words (Bonatti, Peña, Nespor & Mehler, 2005; but see Newport & Aslin, 2004)<sup>1</sup>, while vowels are used for extracting simple grammar-like rules (Toro, Bonatti, Nespor & Mehler, 2007). While the authors of this latter study interpreted their results as evidence that vowels are more important for learning morpho-syntactic grammar-like regularities than consonants, there is a simple alternative explanation. Indeed, the “rules” implemented in that study were based on repetitions of vowels embedded in artificial nonsense words (for example, *tapena*, where the vowel of the first syllable is the same as the vowels of the last syllable; hereafter, we will call such structures *repetition-based*). However, such simple repetition-based structures are learned preferentially when they are made highly salient; in fact, when presented in less salient ways, participants failed to learn them (Endress, Scholl & Mehler, 2005). It is thus possible that participants preferred to use vowels for learning these rules not because vowels are particularly suitable for learning grammatical regularities, but

rather because they carry much more energy and are much more salient than consonants (e.g. Ladefoged, 2001, 2006). In other words, repetition-based structures may be generalized preferentially on the most salient items available, and thus, in a sequence of consonants and vowels, on the vowels; the fact that vowels are a linguistic category may be a mere coincidence.

Here we investigate the question whether generalizations are preferentially observed over vowels because of their specific linguistic functions, or whether the asymmetries observed in earlier experiments were just a side-effect of the vowels' salience. We thus attempt to obtain generalization over consonants by progressively increasing their salience, and by simultaneously decreasing the salience of the vowels. To anticipate our results, while we find reliable rule-learning with vowels even under the most extreme conditions, we do not find significant learning of consonant-based rules in any of the experiments. Still, when pooling together all experiments or removing vowels altogether, a trend towards generalization over consonants emerges. Hence, rules can be learned also over consonants, but, all things being equal, it is much easier to learn rules over vowels.

### **The possible functions of vowels and consonants**

What is the nature of the processes involved in language acquisition and use? At their extremes, two answers have been given to this question. On the one hand, a general mechanism that picks even subtle regularities in the speech signal may eventually give rise

to a fully developed linguistic system with all its complexities. On the other hand, different specialized mechanisms may be needed to extract information from different sources in the signal. This may be true for broad distinctions such as those between learning words and grammatical regularities (Pinker, 1999), but even within the domain of grammar, many different specialized mechanisms may conspire to give rise to a functional language system.

Studying the functional differences between vowels and consonants is a particularly attractive domain in which the general question can be tested, because it can easily be manipulated experimentally. If language fundamentally relies on a single, general, unitary system, both consonants and vowels should fit equally well as input for linguistic computations, and, therefore, there is no need to presuppose representational differences between them. Alternatively, these phonological representations might convey distinct types of information, and may trigger different kinds of specialized computational processes.

From a linguistic perspective, one might indeed expect vowels and consonants to carry different types of information during language processing. While consonants are more readily engaged in lexical processing, vowels play a primary role in marking syntactic constituency (Nespor et al., 2003). Indeed, it is well known that, across different languages, lexical information relies predominantly on consonants. This is particularly apparent in Hebrew and several

other Semitic languages, where lexical roots are made up only by consonants and where, in writing letters code mostly for consonants (while vowels may optionally be specified by diacritics). A related effect is found experimentally in adult participants. When they have to change a phoneme to transform a non-word into a real word, they preferentially replace a vowel, and not a consonant; for example, they are more likely to change *kebra* to *cobra* (a vowel change) rather than to *zebra* (a consonant change; Cutler, Sebastián-Gallés, Soler-Vilageliu, & van Ooijen, 2000; Sharp, Scott, Cutler, & Wise, 2005; van Ooijen, 1996), suggesting that consonants constrain lexical access more strongly.

Vowels, on the contrary, mainly carry prosodic information through pitch changes, or lengthening, among other suprasegmental features. As this information can signal aspects of syntactic structure (Nespor and Vogel, 1986), vowels provide the listener with cues about how units, such as individual words, are to be organized in language. Thus, prosodic cues allow infants to learn important syntactic regularities (Christophe, Nespor, Guasti & van Ooyen, 2003; see also Gleitman & Wanner, 1982; Morgan & Demuth, 1996), although direct evidence for such a role of the vowels is still lacking.<sup>2</sup>

Of course, these differences between vowels and consonants are relative rather than absolute. Many words differ only in their vowels (e.g., minimal pairs such as *pan*, *pen*, *pin* or *ball*, *bell*, *bill*); if vowels were ignored for lexical processing, it would be impossible to keep

these words apart. Likewise, consonants contribute to signaling syntactic constituency in some cases such as the French *liaison*. In French, the final (usually unpronounced) consonant of a word gets resyllabified with the initial vowel of the next word (in case it starts with a vowel) if the two words belong to the same phrasal constituent. For example, in *les ours ont mangé* ('the bears have eaten'), a liaison occurs between *les* and *ours* because these words belong to the same constituent, but not between *ours* and *ont* because these words have a lower level of syntactic cohesion (technically, liaison occurs only within phonological phrases; see Nespor & Vogel, 1986; Selkirk, 1974). Hence, we do not suggest that there is no lexical role for vowels, or no grammatical role for consonants, but rather that, all things being equal, vowels are more important for signaling constituent structure, while consonants are more important for signaling lexical items.

#### **Dissociations between vowels and consonants**

The idea about a functional difference between consonants and vowels has been strengthened by a growing number of experimental results. Drawing from neuropsychological case studies, Caramazza, Chialant, Papasso and Miceli (2000) reported selective impairment of consonants and vowels in two patients. While one of the patients presented important difficulties only in processing vowels, the other patient presented difficulties only in processing consonants, suggesting that different neural substrates might be involved in the

processing of the two phoneme classes. Importantly, such a selective impairment is not due to a failure in processing lower-level acoustic features that differentiate consonants from vowels (e.g. those correlated with the fact that vowels are sonorant); it thus is unclear how the dissociation can be explained without relying on a categorical distinction between the two types of linguistic representations (but see Monaghan and Shillcock, 2003, 2007, and the response by Knobel and Caramazza, 2007).

Evidence for an important role of consonants in lexical processing also comes from laboratory experiments with infants. Nazzi (2005), for example, demonstrated that consonants, but not vowels, play a primary role in word learning for infants at 20 months of age (but see Mani and Plunkett's 2007, investigation of the perception of mispronounced known words). Importantly, such an effect is found even when vowels are compared with either plosive or non-plosive consonants (Nazzi & New, 2007), ruling out the possibility that these results are just produced by differences in sonority levels.

An advantage for consonants over vowels was shown even with adults in statistical learning experiments designed to model word segmentation. In such experiments, participants are typically exposed to a continuous speech stream comprising a series of nonsense words. Thus, the only cue to word boundaries is that syllables within words are more likely to follow each other than syllables across words; that

is, the “transition probabilities” (TPs) within words are higher than between words (Saffran et al., 1996; Aslin et al., 1998).<sup>3</sup> Bonatti et al. (2005) showed that adult learners preferentially perform such statistical computations over consonants than over vowels. After familiarization with a continuous speech stream, participants could effectively segment the words when the only reliable cue was the TPs between the consonants forming them. In contrast, participants could not segment the stream when they had to rely on statistical information between vowels, unless the information was highly redundant (i.e. when only two frames were used for creating the words, so the stream contained immediate repetitions; see also Newport and Aslin, 2004). Moreover, when faced with misaligned consonantal and vocalic information, participants rely more heavily on the former than the latter (Mehler, Peña, Nespor & Bonatti, 2006). Thus, just as consonants seem to be important for lexical processing, they are also the preferred target representations over which words are extracted from continuous speech.

Other authors have argued that these results were mere by-products of acoustical or distributional differences between vowels and consonants in the participants’ native language, and not the result of different processing by the linguistic system. For example, Keidel, Jenison, Kluender and Seidenberg (2007) claimed that differences in the distribution of consonants and vowels in French (the native language of the participants in the Bonatti et al. 2005, and the Mehler

et al. 2006 studies) may explain the above-mentioned results. They showed through corpus analyses that, at least in French, consonant sequences are better predictors of lexical identity than are vowels.<sup>4</sup> Hence, adults may have learned through years of experience, that consonants are more significant for lexical recognition than vowels. Thus these differences could explain why consonants were the preferred target of statistical computations during the artificial language experiments.

Still, there is no evidence that the direction of causation is the one proposed by Keidel et al. (2007) -- and not the opposite one. After all, one has to explain where the distributional differences come from; if they are due to the processing biases proposed in the aforementioned experiments, one has a principled explanation for both the experimental and the distributional results. By Keidel et al.'s (2007) account, Bonatti et al.'s results (2005) may be explained, but the cross-linguistic distributional differences would be a mere accident (see General Discussion, and Bonatti, Peña, Nespor & Mehler, 2007, for more details).

Recent experiments with Italian speakers have shown further evidence for a complementary functional asymmetry between vowels and consonants (Toro et al., 2007). In their experiments, the authors presented participants with an artificial language containing words formed by statistically coherent "consonantal frames", and vowels following a simple underlying structure. After 10 minutes of

presentation of this language, participants readily extracted the words using the consonantal information (as in Bonatti et al. 2005), and generalized the simple rule implemented over the vowels. In contrast, when a different set of participants was presented with a “mirror” artificial language, in which the roles of vowels and consonants were inverted (that is, the statistically coherent frames were implemented over vowels and the underlying structure over consonants), they could extract neither the (statistically defined) words nor the structure. These results confirm the role of consonants as a target of statistical computations used for lexical processing, and suggest a preferential use of vowels for some structural generalizations.

However, one might ask what the source of such differences might be. Consonants and vowels differ in a number of acoustic parameters (e.g. Clements, in press; Ladefoged, 2001, 2006). A very salient acoustic difference between consonants and vowels is that vowels carry more energy than consonants; vowels are thus more salient even to babies (Mehler, Dupoux, Nazzi & Dehaene-Lambertz, 1996). Therefore it may be argued that, whatever element in the speech signal carries more energy, or is more salient within a given sequence, will be privileged for the extraction of structural generalizations. This is particularly true for the sequences used by Toro et al. (2007). Indeed, their rules were based on repetitions of vowels (or consonants); more specifically, the first vowel in a word had to be the same as the last one (as in *tapena*).

Repetitions, however, may not be representative of rule-learning in general (although there certainly are repetition-based regularities, for instance in Semitic languages; McCarthy, 1979); rather, repetitions seem to be processed by a specialized repetition-detecting “primitive” (Endress et al., 2007; Gómez et al., 2000; Tunney & Altmann, 2001). Moreover, repetition-based structures are generalized only under particularly suitable conditions (Endress et al., 2005). It is thus possible that the repetition-based structures in Toro et al.’s (2007) experiments were also extracted just on the most salient items available, and these happened to be the vowels. If so, the asymmetries observed by Toro et al. (2007) may be due simply to the fact that vowels were more salient, with no deep implications for the nature of the representations used to learn more lexical or more grammatical aspects of language

### **The current experiments**

The aforementioned considerations suggest that the observed difference in the roles of consonants and vowels may be reduced to a difference in terms of the energy carried by different elements in the speech signal (and thus their saliency). In the present study we address this possibility by investigating how easily participants would generalize simple structures over consonants that carry more energy than vowels. If the energy-hypothesis is correct, we should observe structural generalizations over consonants just as they have been observed over vowels. This issue was investigated in four

experiments. As a first step, we created an artificial speech stream in which consonants conformed to a simple rule. Importantly, only sonorant consonants (like /n/, that is, consonants that are similarly audible as vowels) were used in this experiment. Such consonants should carry a higher amount of energy than the ones used in previous experiments (because the consonants in the previous experiments were to a large extent stops such as /t/). In Experiment 1, we explored if participants could generalize a simple structure over sonorant consonants. In Experiment 2, we made consonants even more salient by shortening vocalic segments to one third of the duration of consonants, and by concurrently lengthening the consonants. In Experiment 3, the simple structure was implemented over the reduced vowels, to assess participants' generalization abilities over very reduced vowels. Finally, in Experiment 4, vowels were completely eliminated from the speech stream, to test if under this radical modification participants could effectively generalize the structure to new tokens on the basis of consonantal information.

### **Experiment 1: Sonorant Consonants**

In this experiment, we familiarized participants with a speech stream in which words were defined over the vocalic tier, while consonants implemented a simple structure. Importantly, all consonants employed during familiarization were sonorants. After familiarization, participants had to complete two kinds of test trials. In the “recognition” trials, we simply assessed whether participants

recognized the items they had heard. In the “generalization” trials, we asked whether participants would generalize the regularity implemented by the consonants to new tokens. Importantly, in the present study we do not directly address if TPs can be computed over vowels, as other researchers have already explored this issue (Bonatti et al. 2005; Newport & Aslin, 2004). In our experiments, we include small pauses between words; this makes the recognition of individual words possible without the need of relying on statistical computations. Here, we focus on how feasible generalizations over consonants are. Above-chance results in the generalization test would show that using the more salient sonorant consonants is enough for allowing participants to draw structural generalizations over them.

### Materials and Method

#### Participants

Participants were 15 native speakers of Italian. All of them were undergraduate students; none reported hearing deficits, and they were paid for their participation on the study.

#### Stimuli

Stimuli consisted in 12 trisyllabic nonsense words; each syllable had a CV (Consonant-Vowel) structure. In the following, we will call the phoneme sequences carrying statistical information the word *frames*, and the phoneme sequences implementing the structural regularity the *slots*; in Experiment 1, the word frames contained vowels, while the slots carried consonants (because we implemented

the structural regularity over consonants). The words were thus created over two vocalic frames (a\_E\_u; i\_o\_e), and three sonorant consonants (n, l, R) were used for filling the consonant slots. Importantly, these consonants followed an ABA structure (e.g., *RaNeRu*; see Table 1 for the full list). Words were concatenated to create a continuous speech stream. In order to avoid immediate repetitions of vocalic frames, one to three syllables were inserted between the words. These syllables were identical to the ones composing the words, but they were combined randomly, so they did not exhibit any structure that could be extracted. In addition, 25 ms pauses were inserted before and after each word, in order to facilitate the identification of the vocalic frames.

The stream was then synthesized with MBROLA (Dutoit et al., 1996), using an Italian female database (it4). F0 for all phonemes was set to 240 Hz, and their duration were set to 120 ms. Test items were synthesized with the same parameters. For the recognition test, words and part-words were created. Part-words were made of vowels spanning two vocalic frames (as in the ‘part-frame’ u\_i\_o, which is constructed from the last vowel from frame a\_E\_u, and the first two vowels of frame i\_o\_e ), and were filled with the same consonants following the ABA structure as in the words. Vocalic information was thus the only cue for differentiating these test items.

For the generalization test, rule-words and nonrule-words were created. Rule-words were identical to the words, but two new

consonants (j, m) were used for filling the consonantal gaps. Nonrule-words were identical to rule-words, but the two new consonants followed either an AAB or an ABB, and not an ABA structure. These were equally represented in the test pairs. Consonantal information was thus the only reliable cue for a correct discrimination among these test items.

### Procedure

Participants were tested individually in a silent room, wearing headphones. An Apple G4 running PsyScope X (<http://psy.ck.sissa.it>) controlled the experiment. Participants were told that they would hear an artificial language, and that their task was simply to listen to it. After 10 min of familiarization with the speech stream, participants were informed that they would hear pairs of words, and that they would have to decide which word in each pair was more likely to be from the previously heard language. Then, they completed an auditory 2-alternative forced choice test, with two kinds of test pairs: words vs. part-words, and rule-words vs. nonrule-words. The first comparison (*recognition test*) assessed the participants' ability to remember elements from the stream when relying only on vocalic information. The second comparison (*generalization test*) tested their ability to extract the consonantal structure. The 16 test trials (8 for each comparison) were interleaved in semi-random order, with the restriction that no more than two trials of the same type could occur successively. In each trial, test items were separated by a 500 ms

pause.

### Results and discussion

As shown in Figure 1, participants correctly recognized the words in the recognition test well above chance ( $M=70%$ ,  $SD=14.7%$ ),  $t(14)=5.23$ ,  $p<0.001$ . In the generalization test, in contrast, they had no preference for rule-words over nonrule-words ( $M=54.1%$ ,  $SD=15.4%$ ),  $t(14)=1.04$ ,  $p<0.313$ , ns<sup>5</sup>. The use of sonorant consonants (that putatively should be more salient) in the present experiment thus did not improve the generalization of the structural information to new tokens. This suggests that observed differences between consonants and vowels in the present study may not just be a by-product of differences in their relative salience, but most likely a consequence of differential functional roles played by these elements.

Still, one could argue that, compared to sonorant consonants, vowels still carry more total energy, so the energy-hypothesis has not been ruled out. Indeed, we analyzed 5 s samples of the stimuli from Experiment 1 using PRAAT. Onsets and offsets of individual vowels and consonants were marked manually, and the energy computed using the “get energy” function in PRAAT, the energy being defined as the integral of the square of the amplitude between two time points<sup>6</sup>. We found that, on average, vowels still carried 1.78 times more energy than consonants. To use a stronger reversal of the energy relation between consonants and vowels, in the next experiment we thus reduced vowel duration to one third of the duration of each

consonant. At least with this modification consonants should be perceptually more salient than vowels.

### **Experiment 2: Reduced Vowels**

In this experiment, we extended the results obtained in Experiment 1 to assess whether participants can track a structural regularity implemented over consonants. In addition to using relatively salient consonant as in Experiment 1, we added 60 ms to the duration of each consonant, and halved the vowel duration. By any account, consonants should thus be much more salient than vowels, which may facilitate extracting the structural regularity.

#### Materials and Method

##### Participants

Participants were 15 native speakers of Italian. All of them were undergraduate students; none reported hearing deficits, and they were paid for their participation on the study.

##### Stimuli

The stimuli were identical to those of the previous experiment with one exception. The duration of all vowels was reduced from 120 ms to 60 ms, while the duration of all consonants was increased from 120 ms to 180 ms. Duration of vowels in all test items was also only one-third of that of the consonants. With this modification, the relation between consonants and vowels in terms of total energy was clearly inverted. While vowels carried 1.78 times more energy than consonants in Experiment 1, consonant carried 1.34 times more

energy than vowels in Experiment 2.

### Procedure

The procedure was identical to the previous experiment.

### Results and discussion

As shown in Figure 2, participants correctly recognized the words over the part-words ( $M=66.6\%$ ,  $SD=17.4\%$ ),  $t(14)=3.69$ ,  $p<0.005$ . However, they did not show any preference for rule-words over nonrule-words in the generalization test ( $M=55\%$ ,  $SD=11.3\%$ ),  $t(14)=1.7$ ,  $p<0.111$ , *ns*. These results closely replicate those from Experiment 1, as an ANOVA using Experiment (Experiment 1 vs. 2) as a between subject factor and type of test (Recognition vs. Generalization) as a within subject factor showed neither a significant difference between experiments ( $F(1, 28)=0.145$ ,  $p=0.706$ , *ns*) nor a significant interaction between experiments and type of test ( $F(1, 28)=0.229$ ,  $p=0.636$ , *ns*).

Even when consonants were three times as long as vowels, no generalization over consonants emerged. The preferential use of vowels to draw structural generalizations over consonants thus does not seem to depend on their relative salience within the speech stream.

In order to clarify the asymmetric roles of vowels and consonants, we decided to evaluate another prediction: if the advantage for vowels is due to their being more salient than the consonants, one would expect a decline in the generalization performance when this salience difference is reduced. To assess this

possibility, we created a new stream inverting the role played by consonants and vowels. In the new stream, (statistical) frames were implemented over consonants, and the vowels filled the intervening slots following the ABA structure. In this new stream we kept the length of the vowels at one third of that of the consonants, so the former would be much less salient than the latter.

### **Experiment 3: Generalization over reduced vowels**

In Experiment 2, participants failed to generalize a structural regularity carried by consonants although salient (sonorant) consonants were used, and although these were three times as long as the vowels. By any account, this manipulation should encourage the processing of consonants (and discourage the processing of vowels). Still, participants failed to learn the structural regularity, and did not perform any better than in Experiment 1. In Experiment 3, we keep the reduced vowels (and augmented consonants) from Experiment 2, and ask whether generalizations over vowels are possible even under conditions where the vowels are impoverished.

### Materials and Method

#### Participants

Participants were 15 native speakers of Italian. All of them were undergraduate students; none reported hearing deficits, and they were paid for their participation on the study.

#### Stimuli

Stimuli were created as in the previous experiment, except that

the frames were implemented over consonants (n\_l\_s, j\_R\_m), and the intervening slots were filled with vowels (a, e, o) following the ABA structure (see Table 2). That is, in this experiment, the statistical information was carried by the consonants, while the structural regularity was implemented by the vowels. Importantly, the duration of all vowels was kept at 60 ms, while the duration of consonants was 180 ms. Small (25 ms) pauses were inserted between words. In this way, the present stream closely mirrors that used in Experiment 2, with the difference that statistically coherent frames were implemented over the consonants, and the structures to be generalized were implemented over the vowels. During the generalization test, we used two new vowels (I, u) that did not appear during familiarization.

### Procedure

The procedure was identical to the previous experiments.

### Results and discussion

As shown in Figure 3, participants readily segmented the words from the stream using consonantal information; they thus performed well on the recognition test ( $M=69.1\%$ ,  $SD=13.2\%$ ),  $t(14)=5.60$ ,  $p<0.005$ . In a marked contrast to the previous experiments, participants performed reliably above chance even in the generalization test ( $M=61.6\%$ ,  $SD=12.9\%$ ),  $t(14)=3.50$ ,  $p<0.005$  -- even though the vowels were reduced to one third of the consonant duration (and were barely audible). Participants thus reliably generalize simple structures when these are implemented over vowels.

It is also interesting to compare the results of Experiments 2 and 3. As these experiments differ in two variables, namely the carriers of the generalizations (consonants in Experiment 2; vowels in Experiment 3) and the saliency of these carriers (maximized in Experiment 2; minimized in Experiment 3), it is difficult to attribute differences between these experiments to any of these variables. Still, even though the results of Experiments 2 and 3 did not differ significantly ( $F(1, 28)=2.066, p=0.162, ns$ ), the effect size in the generalization condition of Experiment 3 was more than twice as large as the one in Experiment 2 (Cohen's  $d=1.278$  for Experiment 3; Cohen's  $d=0.621$  for Experiment 2). Hence, even when every effort was made to discourage generalizations on vowels and encourage generalizations on consonants, we observe robust generalizations on vowels but not on consonants. Still, the lack of a significant difference between these two experiments also supports the conclusion we will draw below, namely that the difference between vowels and consonants in their ability to support generalizations is not an all-or-none distinction; rather, all things being equal, vowels are more suitable for such generalizations than consonants.

In the final experiment, we test an even more radical implementation of the energy difference between consonants and vowels. In this experiment, we completely eliminate vowels from the familiarization stream, leaving only consonantal segments. If difficulties for making generalizations over consonants result from a

difference in the perceptual salience among phonological representations, participants should be able to easily generalize the simple structure when only consonantal segments are presented.

**Experiment 4: Generalization over consonants with no vocalic segments**

Experiments 1 through 3 showed that, while generalizations over vowels are readily made even when the vowels are greatly diminished perceptually, generalizations over consonants cannot be demonstrated even when consonants are made highly salient. Here, we make a final attempt to observe generalizations over consonants by completely eliminating all vocalic segments from the speech streams.

Materials and Method

Participants

Participants were 20 native speakers of Italian. All of them were undergraduate students; none reported hearing deficits, and they were paid for their participation on the study.

Stimuli

The stimuli were changed relative to the previous experiments because isolated consonants cannot be synthesized with mbrola while avoiding coarticulation. A female native speaker of Italian thus produced the five consonantal segments (/r/, /n/, /l/, /m/, /s/) used in this experiment. We then cut out the steady portion of each consonant for a duration of 180 ms. The stream was constructed with the same structure as that in Experiment 1 and 2, including intervening

elements between words. The consonants *R*, *n* and *l* were used for the familiarization, while consonants *m* and *s* were used for the generalization test. (The phoneme /*j*/, used in previous experiments was replaced by /*s*/ because of difficulties on pronunciation; no recognition test was administered because the vowels were removed from the stream.) All segments were recorded in isolation, using a Sony ECM microphone connected to a laptop computer via a M-Audio pre-amp USB audio interface. Then, they were concatenated to form the stream. All vowels from the sequence used in Experiment 1 and 2 were replaced by 60 ms silences. In order to make the rhythmical units corresponding to words recognizable by the participants, silences of 200 ms (rather than 25 ms) were inserted before and after each word. As no vocalic information was present in this experiment, participants were not presented with the recognition test, because these tests were always performed over the items (consonants or vowels) not used to learn the rules. Hence, participants completed only the eight trials of the generalization test.

### Procedure

The procedure was identical to previous experiments.

### Results and discussion

As shown in Figure 4, results from the generalization test were marginally different from chance ( $M=58.7\%$ ,  $SD=18.1\%$ ),  $t(19)=2.15$ ,  $p=0.044$ , even though it was necessary to run five more subjects than in the other experiments<sup>7</sup>. That is, when only consonantal information

is presented to the participants, they are able to generalize the structure. This result is not at odds with those of Experiments 1 and 2. Indeed, when pooling results from these experiments, a marginal preference for legal items emerges in the generalization test ( $t(29)=1.88$ ,  $p=0.070$ ). Hence, it is indeed possible to draw some structural generalizations over consonants (as one may suspect by considering morphology in language). Note, however, that these results are weak, and that one has to increase the sample size drastically to observe such a result (by 33% in Experiment 4, and by 100% in the pooled experiments). This contrasts markedly with the reliable generalizations over vowels observed in Experiment 3. Hence, while it is to some extent possible to draw generalizations over consonants, vowels are much favored even under extreme conditions.

### **General Discussion**

A long-standing debate in language acquisition research is just how language-specific the underlying computations are. On the one hand, language may rely on a set of language-specific and largely innate abilities; on the other hand, language acquisition may rely in large part on more general, often statistical, learning mechanisms. In the context of this debate, an increasing number of studies have documented striking differences between the role of consonants and vowels. For example, studies with artificial languages have shown that consonants are preferred for the computation of statistical dependencies (Bonatti et al., 2005), while vowels seem to be preferred

for structural generalizations (Toro et al., 2007).

The origins of these asymmetries between vowels and consonants, however, are far from settled. For example, the participants' experience with the distributional properties of their native language may lead to an advantage for consonants in lexical processing (e.g., Keidel et al., 2007; but see Bonatti et al., 2007). Likewise, the advantage for vowels in the structural generalizations observed by Toro et al. (2007) may be due to systematic acoustic differences between vowels and consonants. Indeed, vowels carry more energy than most consonants, and are thus more salient; if the structures used by Toro et al. (2007) are computed preferentially on the most salient items available (for which there is evidence, see Endress et al., 2005), then the "functional" difference between vowels and consonants may simply be due to the higher salience of vowels, with no deeper linguistic implications.

In the present study, we tackled this issue by modifying the saliency of vowels in the speech stream. We attempted to make consonants as salient as possible, and thus to encourage generalizations over them (and simultaneously to discourage generalizations over vowels).

The results showed that when the simple structure was implemented over sonorant consonants, participants could not generalize it to new tokens (Experiment 1). This remained true even when vocalic segments were reduced to one third of the duration of

that of the consonants (Experiment 2). That is, just modifying the perceptual salience of the phonemes by means of phonetic quality and duration is not enough to achieve rapid generalizations over consonants. In contrast, when the simple structure was implemented over vowels, participants generalized the structure to novel items even when the vowel durations were reduced to a third of consonant durations (Experiment 3). In a final, more radical manipulation, we completely eliminated the vocalic contents from the speech stream. Under these conditions, the results revealed marginal evidence for structural generalizations over the remaining consonants (Experiment 4).

In sum, our results demonstrate that it is possible, to some extent, to generalize simple structures over consonants, for example by eliminating all vocalic contents from the stream (or, as in the pooled analyses of Experiments 1 and 2, by doubling the number of participants). However, no such manipulation is required to observe robust generalizations over vowels; even when the vowel duration was reduced to a third of the consonant duration, participants readily generalized the underlying structural relation. Hence, all things being equal, there seems to be a genuine advantage for vowels for extracting certain structural generalizations -- even when all efforts are made to discourage such generalizations.

#### Distributional differences between vowels and consonants

As mentioned in the introduction, some authors attributed

processing differences between vowels and consonants to differences in the respective distributions of these phonetic categories (e.g., Keidel et al., 2007). We believe that such an account is unlikely to explain our results. First, there are no regularities based on repetitions of linguistic elements in Italian (our participants' native language) similar to those used in our experiments. Hence, it is not clear what kinds of distributional differences could account for our results. Second, from a distributional perspective, it is difficult to find an explanation for the fact that the vowel advantage for generalizations is so remarkably resilient to manipulations of the respective salience of vowels and consonants, to the point that participants generalize even over barely audible vowels. After all, one would not expect distributional knowledge to make perceptual factors entirely irrelevant. Hence, we believe that it is reasonable to conclude that the vowel advantage we observe is not due to distributional differences.

More generally, distributional accounts (as the one proposed by Keidel and collaborators, 2007) do not seem to offer a principled explanation for the processing asymmetries between consonants and vowels (see also Bonatti et al. 2007). In fact, such accounts implicitly assume most of Bonatti et al. (2005) proposal: they have to assume that consonants and vowels can be reliably categorized, and are represented on different tiers (so that either transitional probabilities or mutual information calculations can be performed *separately* on a tier). Moreover, these accounts also imply that listeners can actually

perform mutual information calculations separately on vocalic tiers and consonantal tiers over the entire linguistic corpus, and that they can efficiently compare the results of such calculations. However, no direct empirical evidence has been provided for these assumptions.

Keidel et al.'s reliance on the learners' ability to track fine grained distributional regularities present in language may reflect a widespread belief that the presence of statistical regularities in a listeners' input automatically implies that the listener is able to track them. In fact, this is inconsistent with numerous results from animal cognition that demonstrated preferential learning of certain associations over others (e.g., rats easily associate visceral sickness with tastes, but not with places; conversely, they easily associate physical pain with places, but not with tastes; Garcia, Hankins & Rusiniak, 1974). So, even though humans can compute certain statistics over given sequences of elements, it does not follow that they can readily compute *any* statistic over any set of elements. Of course, it is important to ask what kinds of distributional information are possibly contained in the signal, and could be used by an ideal observer. However, given that animals generally are not ideal observers when it comes to statistical regularities, it is equally important to study empirically what kinds of distributional information can actually be processed.

In the case of the processing differences between vowels and consonants, we believe that one needs to provide also a principled

explanation for why consonants are cross-linguistically more important for lexical processing than vowels, and why vowels may be preferentially used for structural generalizations. This can be explained naturally if there are intrinsic processing differences between vowels and consonants, but if these processing differences were just side effects of distributional regularities, this cross-linguistic generalization would be little more than an accident. This, and the fact that in Italian there are no regularities entailing repetitions of items that could have given a distributional bias to our participants, suggest that the vowel advantage for generalizations we observe is not due to distributional knowledge of some sort, but rather reflects some genuine processing differences.

What is the role of vowels for grammar?

Vowels and consonants may play different roles in language acquisition and use. According to Nespor et al. (2003), for example, consonants may be used preferentially for learning and recognizing words, while vowels may carry the prosody of utterances; since prosody correlates with syntactic structure (e.g., Nespor & Vogel, 1986), vowels may thus give cues to constituent structure in speech.

How does such a role of the vowels relate to our results? After all, in the simple repetition-based rules we used, participants do not really have to detect constituent structure; they just have to extract relations among vowels. Moreover, repetition-based relations such as the ones used here seem to be processed by a specialized “primitive”

(Endress et al., 2007); it is thus unclear how such relations mesh with the more abstract syntactic structures for which vowels should be important.

Still, there are linguistic processes that define certain domains, and that bear some resemblance to the rules used in our experiments. Vowel harmony is a case in point. In many languages, vowels within a domain have to agree in one or more features. In Hungarian, for instance, vowels within a word have to be either all front or all back (with certain exceptions). Accordingly, suffixes have different forms for front and back vowels; in the dative case, for example, words with back vowels take the -nak suffix (such as in sor-nak, ‘row’), while words with front vowels take the -nek suffix (such as in sör-nek, ‘beer’).

In our experiments, the identity of the first and the last vowel may define domains in a way similar to vowel harmony. As vowel harmony is much more frequent than consonant harmony in the world’s languages (Nespor & Vogel, 1986), such a function of the vowels may explain the advantage we observed. It will thus be important to find out why precisely vowels are favored in our experiments and in the case of harmonic processes, and whether these two phenomena are related.

Can “structural” saliency account for the vowel advantage?

While it is unclear how our results relate to a prosodic function of vowels, they demonstrate that the vowel advantage for

generalizations cannot be reduced to their “salience”; in fact, it persists even if vowels are made less salient than consonants. A related possibility, however, is that structural generalizations of the type investigated here are preferentially performed over syllabic *nuclei*.<sup>8</sup> As the nuclei have to be more sonorant than either onsets or codas, this possibility would be in some sense a more structural version of the energy hypothesis outlined above.

In our Experiment 3 and in previous experiments (Toro et al. 2007), vowels were always the nuclei of the syllables; likewise, one may consider most of the isolated consonants used in Experiment 4 as essentially nuclear, and results showed some generalization over them. (Similar consonantal nuclei exist in some languages, such as Croatian or Czech.) Note that the sonorance of the nuclei cannot be equated to their salience or their audibility (see Clements, in press), and, in fact, our results demonstrate that the salience of the vowels is not the crucial determinant of the relative ease of the generalization.

It is thus possible that the structural position within a syllable may constitute an important factor for the relative ease of potential structural generalizations. Such generalizations may be favored in nuclei relative to other positions. Again, it is unclear why the nucleus should be particularly suitable for generalizations, but such a possibility should be explored in further empirical work.

Comparative studies provide further evidence that it is not just how easy is to recognize an element in a sequence what determines

the computations that are performed over that element. Indeed, vowels can be recognized more easily than consonants, for example in automatic speech recognition applications (e.g., Benzeghiba et al., 2007). However, in a non-human primate (*saguinus oedipus*) that presumably processes human speech by relying on the acoustic recognizability of speech elements, vowels (rather than consonants, as in humans) are the preferred targets of statistical computations (Newport, Hauser, Spaepen and Aslin, 2004). Hence, if vowels and consonants were processed differently because vowels are more recognizable, one would expect *all* computations to operate better over vowels than over consonants. However, our observations suggest that structures are easily generalized over vowels, while statistical computations are hardly performed over them. This pattern of results can thus not be due to the relative recognizability of vowels and consonants.

Finally, it is important to note that the relative success in Experiment 4 has also a different interpretation. Indeed, the material in Experiment 4 is also the least ‘language-like’, consisting of a stream of consonant sounds separated by silence. It is thus possible that, for non-linguistic input, general learning mechanisms, enable participants to process regularities over these ‘consonants’. In other words, the failure to generalize rules over consonants might be specific to the role of consonants *qua* consonants, that is, as constituents of speech. When these sounds are taken out of a linguistic

context, as in Experiment 4, they might be processed differently therefore allowing to draw simple generalizations over them. In fact, previous research has shown that the same physical sound, when it is perceived in a linguistic or a non-linguistic context, is processed differently and induces different patterns of physiological brain responses (Dehaene-Lambertz et al, 2005, Möttönen et al, 2006). Still, the results from the pooled data of Experiments 1 and 2 suggest that some generalizations over consonants are possible also with more language-like input.

In summary, the present work adds to a growing number of empirical studies that support the hypothesis that consonants and vowels play different roles during language processing (e.g. Bonatti et al. 2005; Caramazza et al. 2000; Cutler et al. 2000; Nazzi, 2005; Owren & Cardillo, 2006; Toro et al. 2007). Importantly, such differences are difficult to account for in terms of lower-level acoustic cues (even though these cues do differentiate vowels and consonants; e.g., Knobel & Caramazza, 2007). There are two interpretations of what might be the source of such differences. They may be due to innate constraints that guide the system to process differently vowels from consonants from very early stages; or acoustical and distributional differences may progressively bias the system towards such differential processing of phonological representations. Be it as it may, the empirical asymmetries between vowels and consonants do

exist, and it will be important to understand their origins to develop a more comprehensive theory of how language is processed.

**Author Notes**

This research was funded by the McDonnell Foundation grant 21002089, by the CEE Special Targeted Project CALACEI (contract 12778, NEST), by the Mind, Brain, and Behavior Interfaculty Initiative at Harvard University, and by PRIN2005 to MN. We would like to thank Jacques Mehler for his valuable insights regarding this study, and Erika Marchetto for lending us her voice for Experiment 4.

**Footnotes**

<sup>1</sup> In Newport & Aslin's (2004) experiments, vowels sequences could be repeated in adjacent words; this manipulation apparently makes vowel sequences pop out, as also Bonatti et al. (2005) observed a sensitivity to non-adjacent vowel relations under these conditions. When these repetitions were removed, however, participants used only consonants but not vowels.

<sup>2</sup> Vowels may carry also other information, such as cues to the identity of the talker (Owren and Cardillo, 2007), but these functions are not relevant to the current experiments.

<sup>3</sup> TPs are conditional probabilities of encountering a syllable after having encountered another syllable. Conditional probabilities like  $P(\sigma_{i+1} = /key/ \mid \sigma_i = /don/)$  are high within words, and low between words ( $\sigma$  denotes syllables in a speech stream).

<sup>4</sup> Technically, in CVCVCV words, the mutual information between the consonant frames and the words is higher than that between the vowel frames and the words.

<sup>5</sup> No direct comparisons between performances in both tasks are included, as we have no independent motivation that would predict the relative performance in them. For example, some rule-like generalizations are affected differently from statistical processes by different manipulations on the familiarization material (e.g., Endress & Bonatti, 2007). While the generalizations studied here are arguably rather different from those studied by Endress & Bonatti, we do not

know how different parameters of the familiarization stream affect the performance on the two tasks, and we cannot be sure whether the relative performance on the two task would be representative of other parameter sets. We thus believe that the use of inferential statistics would not be justified due to these concerns, but, in any case, the relative performance on the two tasks is not crucial for our conclusions.

<sup>7</sup> The results from the first 15 participants did not reach significance;  $M=58.3\%$ ,  $SD=18.7\%$ ;  $t(14)=1.72$ ,  $p=0.106$ , ns.

<sup>8</sup> In phonological theory, a syllable is a hierarchical structure, starting with the *onset*, that is, the initial consonant (cluster), which is followed by the *rhyme*; the rhyme is composed of the nucleus (generally a vowel), followed by a *coda*, that is, the final consonant (cluster). (The only obligatory part is the nucleus; onset and coda are optional in all languages.) In the word /test/, for example, /t/ is the onset, /e/ is the nucleus, and /st/ is the coda; the syllable thus has the structure [t[[e][st]]].

Figure 3: Individual scores and group means during Recognition and Generalization test in Experiment 3. Dots represent the means of individual participants, triangles population averages and the dotted line the chance level of 50%. When familiarized with a speech stream in which a simple rule is carried by vowels whose duration is reduced to one third of that of the consonants, participants readily generalize the rule. They also recognize the items they have heard.
