Traumatic brain injury: integrated approaches to improve prevention, clinical care, and research

Executive summary

A concerted effort to tackle the global health problem posed by traumatic brain injury (TBI) is long overdue. TBI is a public health challenge of vast, but insufficiently recognised, proportions. Worldwide, more than 50 million people have a TBI each year, and it is estimated that about half the world’s population will have one or more TBIs over their lifetime. TBI is the leading cause of mortality in young adults and a major cause of death and disability across all ages in all countries, with a disproportionate burden of disability and death occurring in low-income and middle-income countries (LMICs). It has been estimated that TBI costs the global economy approximately $US400 billion annually. Deficiencies in prevention, care, and research urgently need to be addressed to reduce the huge burden and societal costs of TBI. This Commission highlights priorities and provides expert recommendations for all stakeholders—policy makers, funders, health-care professionals, researchers, and patient representatives—on clinical and research strategies to reduce this growing public health problem and improve the lives of people with TBI.

The epidemiology of TBI is changing: in high-income countries, the number of elderly people with TBI is increasing, mainly due to falls, while in LMICs, the burden of TBI from road traffic incidents is increasing. Data on the frequency of TBI and TBI-related deaths and on the economic impact of brain trauma are often incomplete and vary between countries. Improved, accurate epidemiological monitoring and robust health-economic data collection are needed to inform health-care policy and prevention programmes. Highly developed and coordinated systems of care are crucial for management of patients with TBI. However, in practice, implementation of such frameworks varies greatly and disconnects exist in the chain of care. Optimisation of systems of care should be high on the policy agenda and could yield substantial gains in terms of both patient outcomes and costs to society.

TBI is a complex condition, and strong evidence to support treatment guidelines and recommendations is scarce. Most multicentre clinical trials of medical and surgical interventions have failed to show efficacy, despite promising preclinical results. At the bedside, treatment strategies are generally based on guidelines that promote a one-size-fits-all approach and are insufficiently targeted to the needs of individual patients. Attempts to individualise treatment are challenging owing to the diversity of TBI, and are hampered by the use of simplistic methods to characterise its initial type and severity. Advances in genomics, blood biomarkers, magnetic resonance imaging (MRI), and pathophysiological monitoring, combined with informatics to integrate data from multiple sources, offer new research avenues to improve disease characterisation and monitoring of disease evolution. These tools can also aid understanding of disease mechanisms and facilitate targeted treatment strategies for individual patients.

Individualised management in the postacute phase and evaluation of the effectiveness of treatment and care processes depend on accurate quantification of outcomes. In practice, however, the use of simplistic methods hinders efforts to quantify outcomes after TBI of all severities. Development and validation of multidimensional approaches will be essential to improve measurement of clinical outcomes, for both research and patient care. In particular, we need to find better ways to characterise the currently under-recognised risk of long-term disabling sequelae in patients with relatively mild injuries.

Prognostic models are important to help clinicians to provide reliable information to patients and relatives, and to facilitate comparative audit of care between centres and countries. There is an urgent need for further development, validation, and implementation of prognostic models in TBI, particularly for less severe TBI.

This multitude of challenges in TBI—encompassing systems of care, clinical management, and research strategy—demands novel approaches to the generation of new evidence and its implementation in clinical practice. Comparative effectiveness research (CER) offers opportunities to capitalise on the diversity of TBI and systems of care and enables assessment of therapies in real-world conditions; high-quality CER studies can provide strong evidence to support guideline recommendations. The global challenges posed by TBI necessitate global collaborations and a change in research culture to endorse broad data sharing.

This Commission covers a range of topics that need to be addressed to confront the global burden of TBI and reduce its effects on individuals and society: epidemiology (section 1); health economics (section 2); prevention (section 3); systems of care (section 4); clinical management (section 5); characterisation of TBI (section 6); outcome assessment (section 7); prognosis (section 8); and new directions for acquiring and implementing evidence (section 9). Table 1 summarises key messages from the Commission and provides recommendations to advance clinical care and research in TBI.

We must increase awareness of the scale of the challenge posed by TBI. If we are to tackle the individual and societal burden of TBI, these efforts need to go beyond a clinical and research audience and address the public, politicians, and other stakeholders. We need to develop and implement policies for better prevention and systems of care in order to improve outcomes for individuals with TBI. We also need a commitment to substantial long-term investment in TBI research across a range of disciplines to determine best practice and facilitate individualised management strategies. A combination of innovative research methods and global collaboration, and ways to effectively translate progress in basic and clinical research into clinical practice and public health policy, will be vital for progress in the field.

**Introduction**

Traumatic brain injury (TBI) is defined as an alteration in brain function, or other evidence of brain pathology, caused by an external force. It varies in severity from mild TBI (which includes concussion) to moderate and severe TBI. Severe TBI has a high mortality rate, estimated at 30–40% in observational studies on unselected populations. Survivors experience a substantial burden of physical, psychiatric, emotional, and cognitive disabilities, which disrupt the lives of individuals and their families, and pose huge costs to society. Such disabilities are not restricted to severe cases, but also occur frequently after moderate or mild TBI.

TBI is a growing public health problem of substantial proportions. More than 50 million TBIs occur worldwide, with an estimated 60% of all TBIs occurring in low-income and middle-income countries. 

### Table 1: Key messages and recommendations

<tbody>
<tr>
<td>1, 3, 4, 9</td>
<td>Worldwide, TBI is a leading cause of injury-related death and disability, with a devastating impact on patients and their families</td>
<td>Concerted efforts to address this vast global health problem should focus on policies aimed at reducing the burden and impact of TBI, through better prevention, improved access to care, and promotion of clinical research to improve treatment standards.</td>
</tr>
<tr>
<td>1, 4</td>
<td>In low-income and middle-income countries, the incidence of TBI due to traffic incidents is increasing, while in high-income countries, TBI increasingly affects elderly people, mostly due to falls, however, methodological variations confound comparisons of epidemiological patterns of TBI between regions, countries, and continents</td>
<td>An international consensus is needed on definitions and standardised epidemiological monitoring of TBI, to allow accurate measurement of incidence, prevalence, and mortality, and comparison of rates of access to community, hospital, and residential care.</td>
</tr>
<tr>
<td>1</td>
<td>TBI might represent an important modifiable risk factor for epilepsy, stroke, and late-life neurodegenerative disease</td>
<td>Studies are needed, in children and adults, to better understand links between TBI of all severities and an increased risk of later neurological diseases.</td>
</tr>
<tr>
<td>2</td>
<td>TBI results in substantial health-care and societal costs</td>
<td>More effective strategies for TBI prevention are urgently needed, and could deliver cost savings that help to fund research and improved access to health care for TBI.</td>
</tr>
<tr>
<td>3</td>
<td>Second or subsequent concussions that occur before recovery from an initial concussion can be associated with more severe symptoms and more prolonged recovery than a single injury of similar severity</td>
<td>Any risk of an early second injury after even a mild TBI should be avoided; professional sporting organisations should set an example for children and amateur athletes by immediately removing from play anyone with a suspected concussion.</td>
</tr>
<tr>
<td>4</td>
<td>Access to healthcare is often inconsistent between centres, regions, and countries, especially for acute and postacute care</td>
<td>Health-care policies should aim to improve access to acute and postacute care to reduce the effects of TBI on patients, families, and society.</td>
</tr>
<tr>
<td>5</td>
<td>Evidence underpinning guidelines for medical, surgical, and rehabilitation interventions for TBI is weak</td>
<td>Robust evidence is needed to inform guidelines on medical, surgical, and rehabilitation interventions, and hence improve outcomes for patients with TBI.</td>
</tr>
<tr>
<td>6</td>
<td>Methods of diagnosis and classification of patients with TBI are insufficient to permit targeting of current and new therapies to the needs of individual patients</td>
<td>Research is needed to improve the precision of diagnosis, classification, and characterisation of TBI using multidomain approaches.</td>
</tr>
<tr>
<td>7</td>
<td>Trauma disturbs the brain in complex ways, affecting multiple outcome domains</td>
<td>Multidimensional outcome constructs that quantify the overall burden of disability from TBI need to be developed and validated to guide improved clinical management and support high-quality research.</td>
</tr>
<tr>
<td>8</td>
<td>A validated set of quality indicators is essential for the benchmarking of quality of care, but none exists for TBI</td>
<td>Efforts are needed to develop a set of quality indicators for TBI that includes structure, process, and outcome metrics.</td>
</tr>
<tr>
<td>9</td>
<td>Substantial between-centre variability in treatment and outcome in TBI offers unique opportunities for comparative effectiveness research to improve the strength of evidence</td>
<td>Comparative effectiveness research should be supported to identify best practices and to improve the level of evidence for systems of care and diagnostic and therapeutic interventions.</td>
</tr>
<tr>
<td>9</td>
<td>Coordinated research efforts on a global basis are needed to address the growing public health problem of TBI</td>
<td>A commitment of governmental and non-governmental funding bodies, as well as industrial partners, is needed to foster global collaborations and to establish national and international biorepositories and databases that could facilitate future TBI research.</td>

TBI=traumatic brain injury.
internationally each year. The incidence of TBI in high-income countries (HICs) has increased in the elderly to a greater extent than might be expected from demographic ageing, whereas increased use of motorised vehicles in low-income and middle-income countries (LMICs) has led to a rise in TBI from road traffic incidents. Across all ages, TBI represents 30–40% of all injury-related deaths, and neurological injury is projected to remain the most important cause of disability from neurological disease until 2030 (2–3 times higher than the contribution from Alzheimer’s disease or cerebrovascular disorders). TBI costs the international economy approximately US$400 billion annually, which, given an estimated standardised gross world product of US$73·7 trillion, represents approximately 0·5% of the entire annual global output.

Wide variations in the clinical manifestations of TBI are attributable to the complexity of the brain, and to the pattern and extent of damage, which depend on type, intensity, direction, and duration of the external forces that cause TBI. In traffic-related injuries, acceleration–deceleration forces can result in immediate shearing of connecting nerve fibres or trigger progressive loss of connectivity over time. Forces generated by a fall or blow to the head more often cause bruises (contusions). Individuals can react very differently to similar injury forces. Conceptually, it is important to distinguish between the primary damage, inflicted at the time of injury, and secondary damage, which evolves over hours, days, weeks, months, or even over a lifetime in some cases. Secondary damage is driven substantially by host responses to the primary injury. As a bruised ankle might swell following injury, so can the brain. The difference is that the brain is contained within the rigid skull and any swelling results in increased pressure within the skull (intracranial pressure [ICP]). This increased pressure, in turn, can lead to life-threatening shifts of brain structures or impair blood flow through the brain, resulting in ischaemia and deprivation of oxygen to the brain. TBI is best viewed as a collection of different disease processes (figure 1), with different clinical patterns and outcomes, each requiring different approaches to diagnosis and management.

TBI might also confer a long-term risk for cognitive impairment and dementia, stroke, parkinsonism, and epilepsy, and is associated with an increased long-term mortality rate compared with rates for the general population. These risks also occur in milder forms of TBI, especially after repetitive injuries.

Figure 1: The multiple faces of traumatic brain injury

(A) Sheared brain: the typical picture of axonal injury on computed tomography (CT, upper panel) and magnetic resonance imaging (MRI) using susceptibility-weighted imaging (lower panel) in an adult patient with traumatic brain injury (TBI). Note the greater sensitivity of MRI for detection of microbleeds (green arrows), which are commonly associated with diffuse axonal injury. (B) Bruised brain: contusional brain injury (green arrows) on CT in two elderly patients with TBI, particularly located in the frontal and temporal regions. (C) Brain under pressure: a typical epidural haematoma (bleeding between the skull and outer coverings of the brain; green arrow) on CT in two adult patients with TBI. The haematoma in the upper panel is an example of an injury that compresses the brainstem (white arrow); the haematoma in the lower panel causes midline shift and indirect compression of the brainstem due to raised intracranial pressure. Both are life-threatening and constitute a neurosurgical emergency. Patients can recover completely if operated on quickly. (D) Disconnected brain: white matter tracts measured with diffusion tensor imaging and visualised by MR tractography in an adult patient with TBI 12 days after the injury (upper panel) and at 6-month follow-up (lower panel). Note the extensive progressive late white matter loss. Panel D reproduced from Sener and colleagues, by permission of Oxford University Press.
Accumulating knowledge makes it clear that TBI is not a single event, but can be a chronic and often progressive disease with long-term consequences. Even after an ostensibly good recovery, patients might have to live with a continuing process of coping and adaptation (panel 1).

Clinical progress has not kept pace with the rising global burden of TBI and recognition of the prolonged effects of injury. The most recent major breakthrough in clinical management was the introduction of computed tomography (CT) scanning into routine care—now more than 40 years ago. Since then, there have been no major improvements in outcome after TBI in HICs with developed trauma systems. This lack of progress can be attributed to many factors, in both the policy and the clinical domains. Public and political awareness of the magnitude of the problems caused by TBI—including the clinical impact on patients, families, and society, and public health burden and costs to society—is low. Additionally, there has been insufficient clinical recognition of the complex heterogeneity of TBI, in terms of disease type, outcome, and prognosis. Treatment approaches do not sufficiently recognise specific needs of individual patients, and disconnects exist along the chain of trauma care, especially between acute and postacute care. Clinical research has, until recently, focused mainly on more severe TBI, but the vast majority (70–90%) of patients suffer from mild TBI. Although the individual impact of mild TBI is less, the category as a whole makes the largest contribution to the global burden of disability, and timely intervention and structured follow-up in this group could deliver substantial gains in public health and societal costs.

We believe that strategic global collaboration is required at several levels. First, policy makers and funders need to support an integrated effort by the entire neurotrauma community to identify improved approaches to TBI prevention and best practices for systems of care and management. Second, research strategies are needed to enable better characterisation of TBI through the disease course, and emerging research paradigms and tools need to be incorporated into clinical studies. In addition to the undeniable need for increased research funding, organisational improvements across the chain of trauma care will be essential to maximise the benefits of developing global research collaborations and to achieve the best possible returns on research funding. Finally, we need an intensive knowledge-transfer exercise to implement the outputs of these efforts in clinical practice. Such implementation requires that we inform and involve health policy makers, health-care professionals, and the general public about the magnitude of the problem, the extent of (and gaps in) our current knowledge, and emerging advances.

The overall aims of this Commission are to set out directions for improvements in clinical care and to establish research priorities. We aim to provide a foundation for implementation of policy measures that minimise the risk of TBI and maximise chances of recovery when it does happen. This manuscript represents the efforts of a consortium of leading health-care professionals with expertise in epidemiology, health economics, diagnosis, treatment, outcome assessment, biology, and ethics, all of whom are involved in the International Initiative for Traumatic Brain Injury Research (InTBIR) studies, with input provided by other collaborating specialists and, crucially, by patients. In conjunction with this Commission, four Series papers on clinical advances in TBI, aimed at health-care professionals, have been published in recent issues of The Lancet Neurology.
Section 1: Epidemiology of TBI

Globally, TBI is a leading cause of injury-related death and disability,3,4,5 imposing a huge burden on patients, their families, and society. In LMICS, the rising burden of TBI from increases in road traffic incidents predominantly affects young individuals.7 The changing epidemiology of TBI in HICs is attributable to a high and increasing incidence in paediatric and elderly subpopulations.4–6,32–34 Increases in TBI are also reported in the contexts of sports35–37 and armed conflict.38

Reported incidence and mortality rates for TBI vary greatly between countries and regions. This partly reflects variations in acquisition and reporting of epidemiological data, and makes interpretation of official statistics difficult. Definitions of TBI vary considerably (panel 2),1,39,40 resulting in difficulties in diagnosis and case ascertainment, and its current classification is fairly crude, relying only on assessment of level of consciousness (figure 2). Relatively few epidemiological studies of TBI report age-adjusted data, which are required for valid comparisons between countries with differing population demographics. Moreover, for many countries or regions, epidemiological studies have not been done or available data capture only a proportion of all TBIs, so the scale of the problem is likely to be considerably greater than current figures suggest. Addressing the vast global health problem posed by TBI requires substantial efforts to correct current deficiencies in epidemiological monitoring. Robust epidemiological data are essential to quantify the public health burden of TBI, to inform policies for prevention, to understand the health-care needs of patients, and to allow appropriate allocation of health-care resources.

In this section, we provide an overview of the epidemiology of TBI, highlight the increasing burden of TBI in LMICs, and review the evidence for changing patterns of epidemiology in HICs. We propose ways to enhance epidemiological data collection and to improve the usefulness of such data in informing health-care policy and prevention programmes.

Incidence of TBI

Reported incidence rates of TBI across the world vary considerably, with substantial gaps in robust data for many parts of the world, particularly LMICS, where TBI rates are likely to be high (figure 3).1,30,31,32,33,34 Substantially higher incidence rates for TBI are seen in population-based studies with broad definitions of TBI (811–979 per 100 000 people per year)1,31,33 than in studies based on hospital discharge rates (47.5–643.5 per 100 000 people per year).30,33 Projections from such studies suggest that 50–60 million new TBI cases occur annually worldwide, over 90% of which are mild TBIs.5 For the European Union (EU; 28 Member States), we estimate that at least 2.5 million new cases of TBI occur each year (table 2), and in the USA, the total number of patients with a new TBI has been reported to approach 3.5 million per year.9 Results from a recent study using standardised Eurostat data from 24 European countries suggested that 1.5 million TBI-related hospital discharges and 57 000 TBI-related deaths occurred in 2012 in the 28 Member States of the EU.9,10 The pooled age-adjusted incidence of TBI (hospital discharges) was 287.2 per 100 000 people per year, with enormous differences between countries (figure 4) that are likely to reflect differences in study methodology rather than true variation.10

Panels

Panel 2: Definitions of traumatic brain injury

World Health Organization definition

“...an acute brain injury resulting from mechanical energy to the head from external physical forces”, excluding manifestations relating to “drugs, alcohol, medications, caused by other injuries or treatment for other injuries (eg, systemic injuries, facial injuries or intubation), caused by other problems (eg, psychological trauma, language barrier or coexisting medical conditions) or caused by penetrating craniocerebral injury.”

This broad definition of traumatic brain injury (TBI) is widely used, but some ambiguity exists as to what constitutes “an acute brain injury”. Furthermore, the definition focuses on mild TBI, and therefore excludes patients with penetrating craniocerebral injury.

American Congress of Rehabilitation Medicine definition

“A patient with mild traumatic brain injury is a person who has had a traumatically induced physiological disruption of brain function, as manifested by at least one of the following: (1) any period of loss of consciousness; (2) any loss of memory for events immediately before or after the accident; (3) any alteration in mental state at the time of the accident (eg, feeling dazed, disoriented, or confused); and (4) focal neurological deficit(s) that may or may not be transient; but where the severity of the injury does not exceed the following: loss of consciousness of approximately 30 minutes or less; after 30 minutes, an initial Glasgow Coma Scale score of 13–15; and posttraumatic amnesia (PTA) not greater than 24 hours.”

This definition is specific to mild TBI and excludes patients with more severe TBI, which conflicts with the concept that the severity of TBI lies along a continuum. Note that the term “concussion” is often used synonymously with “mild TBI”.11 See figure 2 for classification of clinical severity with the Glasgow Coma Scale.

National Institute of Neurological Disorders and Stroke definition

“TBI is defined as an alteration in brain function, or other evidence of brain pathology, caused by an external force.”

This statement acknowledges potential confounders to TBI diagnosis, and suggests that symptomatology, imaging findings, details of the incident, and wider context should all be taken into account to inform diagnosis.1

Figure 2: Classification of clinical severity of traumatic brain injury with the Glasgow Coma Scale

Responses are assessed in three domains (eye, motor, and verbal) and individual scores are added to give a Glasgow Coma Scale (GCS) sum score for mild, moderate, or severe traumatic brain injury (TBI).47

For more on Eurostat see http://ec.europa.eu/eurostat

For the Lancet Neurology Commission
The US Centers for Disease Control and Prevention (CDC) surveillance studies of TBI have used standardised case definitions and methods of data collection for nearly three decades,52,61,62 and focus on emergency department visits, admissions to hospital, and deaths. Recent data indicate that, each year, over 2 million Americans with TBI are treated and released from an emergency department, nearly 282,000 are admitted to hospital and discharged alive, and 56,000 die as a consequence of TBI.32,52

Figures for the EU and the USA are discordant (table 2). Relative to population size (EU 510 million, US 321 million), the number of deaths due to TBI is lower in the EU than in the USA. Much of this difference might be explained by the high death rate from firearms-related wounds in the USA—estimated at 10·5 per 100,000 people per year—since head wounds are often involved in fatalities.63 This rate of firearms-related deaths is exceeded only by some Latin American nations and is far higher than the average rate in the EU of 1·1 per 100,000 people per year.64

Relative to population size, the reported number of hospital admissions for TBI is more than 3 times higher in the EU than in the USA.30,32,52,65 By contrast, the reported number of new cases per year in the USA, adjusted for population size, is double that of the best estimate of new cases in the EU (table 2).30–33,52,57–60 These differences are probably mainly due to methodological diversity in epidemiological studies, including differences in case ascertainment, although variation in hospital admission policies might also be a factor. Discrepancies and differences in epidemiological findings and health-economic

Estimates for the EU are based on four studies.30,33,57,58 Estimates for the USA are based on five studies.30,32,52,59,60 These numbers are an approximation; numbers from original reports have been rounded to the nearest 1000. TBI=traumatic brain injury.
Prevalence of TBI

Accurate data for TBI prevalence are even more limited than those for incidence, particularly for LMICs. A meta-analysis of 15 prevalence studies revealed that of a total sample of 25,134 adults, 12% had experienced a serious TBI with loss of consciousness, with men being at more than double the risk of women. Prevalence is higher in young adults—eg, one birth-cohort study showed that more than 30% of participants had experienced at least one TBI requiring medical attention before the age of 25 years. In view of the increasing incidence of TBI in elderly populations, it is reasonable to conclude that about half the world’s population have had a TBI. This inference is supported by the results of a population-based survey with random sampling in Colorado, USA, in which 42% of respondents reported at least one TBI in their lifetime (36% mild and 6% moderate-to-severe injury). TBI has a substantial ongoing health impact: in the USA, an estimated total of 3-17 million people live with permanent sequelae of a past TBI. TBI is among the top three specific neurological conditions accounting for neurodisability globally, both at present and in projections up to 2030. Concerted efforts are required to reduce this high burden of disability.

Mortality and years of life lost from TBI

Death rates after TBI are variably reported as mortality rates or case-fatality rates. Mortality rates relate the number of deaths over a specific timeframe to the population size—eg, the number of deaths per 100,000 people per year. Case-fatality rates refer to the proportion of reported cases with a specified disease or condition, which are fatal within a specified timeframe—eg, the death rate for patients admitted to hospital with TBI during the acute treatment phase. Case-fatality rates are therefore greatly influenced by case-mix, and will be higher for patients with severe TBI than for those with mild TBI. These parameters capture the number of deaths relative to different populations at risk. However, the public health consequences of TBI deaths are better captured by the concept of years of life lost (YLL), which gives an estimate of the number of years a person would have lived if he or she had not died prematurely—eg, from a TBI.

Reported mortality rates for TBI vary widely between countries. According to the US CDC, population-based mortality due to TBI was 17.1 per 100,000 people in 2010. In China, population-based mortality for the year 2013 was 13.0 per 100,000 people. Using Eurostat data from 25 European countries, Majdan and colleagues calculated a pooled age-adjusted mortality rate of 11.7 per 100,000 people (95% CI 9.9–13.6) in 2012, but reported a wide range from 3·6 per 100,000 people in Turkey to 21·8 per 100,000 people in Switzerland. They noted that methods (eg, diagnostic criteria and case ascertainment) varied substantially between countries, and studies did not always differentiate deaths directly due to brain injury from those due to other complications. Most studies have focused on severe TBI, usually defined according to the Glasgow Coma Scale (GCS; figure 2), and little is known about the contribution of non-severe TBIs to mortality. Although establishing a global mortality rate is difficult, our best estimate is that TBI causes in the region of a million deaths a year. Patterns of TBI mortality depend on age and injury mechanisms and can change over time. HICs show declining rates of traffic-related TBI deaths and increasing death rates from fall-related TBI. The highest mortality rate is in adults over 60 years of age. A recent meta-analysis of 24 studies in patients with moderate and severe TBI, with a pooled sample size of 93,115 older adults (≥60 years), revealed an in-hospital case-fatality rate of 57% (95% CI 43–71) and a 6-month case-fatality rate of 75% (62–84).

Studies with estimates of YLL attributable to TBI are scarce: the YLL related to TBI has been estimated at 118,207 years for the Netherlands (2010–2012) and at 14,386 years for New Zealand (2010). A recent analysis of data from 16 European countries revealed a total of almost 375,000 YLL related to TBI in 2013, which translates to a pooled age-adjusted rate of 259·1 (95% CI 205·8–312·3) YLL per 100,000 people per year and to an average of 24·3 (22.0–26·6) YLL with each TBI death. Nearly 74% of all YLL due to TBI affected individuals in age groups with potential to work (15–64 years).

The high acute mortality in severe TBI is well recognised: TBI is a contributing factor in 37% of all injury-related
Panel 3: Traumatic brain injury—a big problem in big countries

**China**

China has a population of 1·3 billion. No reliable nationwide data are available on the incidence of traumatic brain injury (TBI). Several large-scale population-based studies, conducted in the 1980s,66–68 report an incidence of head trauma of 5·4–6·1 per 100,000 people per year. This incidence is much lower than the estimates reported for other countries, and probably reflects incomplete case ascertainment. The current burden of care for TBI is very high in many Chinese hospitals, with many neurological departments nearly exclusively treating TBI.

Road traffic incidents are the most common cause of TBI (54%), followed by falls (32–33%) and violence (9–11%).66,67 The high rate of traffic-related TBI is unsurprising, as car ownership has increased at a compound rate of about 12% per annum between 1980 and 2009, resulting in a 35-times increase in car ownership (from 0·018 to 0·628 per capita).67

In response to a high rate of traffic-related deaths and injuries associated with alcohol use, the Chinese ministry of public safety issued the national alcohol penalty law in 2011, which stated that all drunk drivers should be sent to jail.67 Since then, alcohol-related accidents have declined rapidly—eg, a recent study, using data from China’s Disease Surveillance Points system, reported a decrease in TBI mortality from 17·06 per 100,000 people in 2008 to 12·99 per 100,000 people in 2013.72 Implementation of the law on drinking and driving is likely to have contributed to this decrease in mortality.

Falls as a cause of TBI seem to be increasing from a rate of 12% in 200466 to 29% in 2008–2009.69 Interpersonal violence is among the top three leading causes of TBI in China,69 but gunshot wounds as a cause of TBI are rare (<1%). According to Chinese law, a Chinese citizen or foreigner in China is sentenced to jail if he or she owns, sells or buys, or transports firearms.

**India**

India has a population of 1·3 billion. Accurate data on TBI epidemiology in India are lacking, and there is no national trauma registry. The National Crime Records Bureau in India reported a total of 413,457 accidental deaths in 2015,70 and this is likely to be an underestimation of the actual number.71 This represents an increase in accident-related deaths of 49% over the period 2004–2015, while population growth was 16·4%. Approximately 50% of trauma deaths are likely to be related to TBI, according to the Towards Improved Trauma Care Outcomes (TITCO) trauma registry of Indian urban university hospitals (Roy N, BARC Hospital, Mumbai, India, personal communication), which would imply that about one TBI-related death occurs every 3 min. Nearly a million people are disabled owing to TBI in India each year,69 and between 60% and 70% of TIBIs result from road traffic incidents.72,73

Poor recognition and inadequate early management of brain injuries, delays between injury and reaching specialist care (only 24% arrive within 1 h, 30% arrive within 2–3 h, and 24% take more than 24 h), lack of adequate prehospital care services, and limited trauma care services might account for poor outcomes in individuals who sustain a TBI in India.72,73 High-level care can be provided in the few specialised neurotrauma centres, but access to such resources is scarce.72 Many districts lack computed tomography (CT) scanners and crucial equipment such as mechanical ventilators, and a great need exists for rehabilitation services.76,80,82,83

Towards improved epidemiological monitoring

Reliable epidemiological data and improved awareness of TBI in India and China are sorely needed to understand fully the scale of the problem, to drive forward prevention programmes (section 3), and to guide provision of health-care resources for the management and ongoing care of patients (section 4). Accomplishing this will be no simple task. Experience in Europe has shown that despite uniform approaches to collection and analysis of administrative data, wide variations in reported incidence and mortality rates exist between countries,73 restricting interpretation of such data. Close interaction between governmental authorities and health-care professionals is required to derive the best model for capturing the extent of the burden of TBI in these large countries.

Deaths in the EU30 and about a third (30–5%) of all injury-related deaths in the USA (with an average reported number of 169,000 injury-related deaths per year in the USA between 2002 and 2006).64 Long-term mortality in TBI is a substantial, but less well recognised, problem: for many years, TBI survivors experience mortality rates that exceed those in age-matched and sex-matched population controls and in similar cohorts without TBI trauma.66 In a Scottish study of patients aged 15–54 years, the death rate 13 years after TBI was more than 6 times higher than in community controls.68 The Global Burden of Disease studies showed a pooled standardised mortality ratio of 2·18 (95% CI 1·88–2·52) for TBI survivors.77 This excess mortality is in part attributable to expected consequences and associations with TBI, such as epilepsy, but also due to an increased risk of illnesses not directly related to injury, such as pneumonia, septicemia, and respiratory and digestive disorders.77 TBI has been shown to shorten life expectancy by 6 years.77

TBI as a risk factor for later neurological disease

TBI might be a major risk factor for late neurodegenerative disorders such as dementia and Parkinson’s disease, reinforcing the view that TBI can evolve into a progressive lifelong illness.78 A meta-analysis of 15 case-control studies reported a pooled odds ratio of 1·58 (95% CI 1·21–2·06) for development of later-life dementia after a single TBI with loss of consciousness.79 Autopsy studies have shown accelerated development of tau and amyloid pathology in a third of TBI survivors who died of non-TBI-related

www.thelancet.com/neurology Published online November 6, 2017 http://dx.doi.org/10.1016/S1474-4422(17)30371-X
causes decades after the initial injury. TBI sustained after 55 years of age is associated with a 44% increased risk of developing Parkinson’s disease within the subsequent 5–7 years. A population-based clinical and neuropathology survey confirmed this association for the incidence and progression of parkinsonism, and for Lewy body disease, but not for dementia or dementia-related pathology more generally. By contrast, a recent Finnish study showed that in working-aged people, a history of moderate-to-severe TBI is associated with an increased risk of future dementia, but not Parkinson’s disease or amyotrophic lateral sclerosis.

TBI-associated dementia might be clinically and pathologically distinct from Alzheimer’s disease, with more patients experiencing behavioural symptoms such as depression, agitation, and irritability. Preliminary estimates of population-attributable risk, based on TBI prevalence and relative risk of dementia in TBI survivors, indicate that as much as 5–15% of the population burden of dementia could be due to brain trauma.

Repetitive mild TBI can result in a distinct pathology known as chronic traumatic encephalopathy (CTE). In his landmark clinical account of punch-drunk syndrome in boxers, Martland provided the first clinical description of progressive neuropsychiatric sequelae associated with repetitive mild TBI, and the neuropathological substrate was detailed by Corsellis and colleagues. Recent autopsy studies have found similar associations with clinical features in non-boxer athletes from sports with high risk of concussion or mild TBI, such as American football, ice hockey, soccer, and rugby, as well as in ex-military personnel. In these descriptions, the distinguishing clinical features comprise a triad of behavioural, mood, and cognitive deficits, which have been variably associated with pyramidal and extra-pyramidal dysfunction and cerebellar impairment in retired professional football players, and might represent the clinical correlate of CTE pathology. The risks of developing CTE for individuals who play these sports remain unclear. A recent autopsy series reported a rate of CTE of 99% in professional American football players, but this was a highly selected group of individuals, and extrapolation to more generalised estimates of risk is not appropriate. By contrast, a recent population-based longitudinal study reported that playing high-school football was not associated with poorer cognition or worse mental health outcomes in older adulthood compared with a control cohort.

In addition to the late consequences of (possible) repetitive mild TBI, it is increasingly apparent that a proportion of individuals with a clinically established diagnosis of even a single TBI can experience ongoing cognitive decline in the medium term (months to years), rather than showing clinical improvement or remaining stable. Long-term disability could change with time, and age-related decline in cognitive reserve might unmask the consequences of an earlier TBI. A 13-year longitudinal study in Glasgow, Scotland, reported such late deterioration in up to 50% of patients with TBI, which can be visualised by progressive changes on advanced neuroimaging. Furthermore, a decline in outcomes from 1 year to 5 years after injury was recently reported in 36 of 50 (72%) US military service members with concussive blast TBI.

Other evidence suggests that TBI is an independent risk factor for stroke. A retrospective case-control study from Taiwan showed that a past history of TBI doubled the risk of stroke (hazard ratio 1.98; 95% CI 1.86–2.11) and increased post-stroke mortality (odds ratio 1.57; 95% CI 1.13–2.19).

Post-traumatic epilepsy is a well recognised complication of TBI. Compared with the general population, there is a 1.5-times increased risk of developing epilepsy after mild TBI and a 17-times increased risk after severe TBI, which results in a 30-year cumulative risk of post-traumatic epilepsy that ranges from 2–1% for mild TBI to 16–7% for severe TBI. Moreover, TBI accounts for about 5% of cases of epilepsy in the general population.

The association between TBI and an increased risk of late neurological disease remains poorly understood, largely owing to the retrospective nature and limited scope of many past studies and small cohort sizes in recent, more comprehensive reports. There is a pressing need for research into the incidence, clinical presentations, and risk factors in TBI-associated neurological diseases and their overlap with existing, better characterised disorders, such as Alzheimer’s disease and Parkinson’s disease.

Changing epidemiological patterns of TBI

The epidemiology of TBI in HICs is changing. TBI due to traffic-related incidents has decreased, and falls are now the leading cause of TBI, particularly in elderly patients. The median age of patients with TBI in HICs has nearly doubled since the 1980s. Since the 1970s, a decrease in hospital admissions for TBI in elderly patients. In Europe, a decrease in overall TBI incidence since the late 1990s, mainly due to a decrease in traffic-related injuries, has been reported in Scotland, UK, Spain, and Portugal. Most of these studies reported an increase in incidence of TBI in elderly patients. The observed decrease in hospital admissions for TBI in Europe has not been reported in other HICs such as Canada and the USA. Since the 1970s, a decrease in mortality due to TBI has been reported in many studies, mainly due to fewer traffic-related deaths.

The results of a systematic review of TBI mortality over the past 150 years suggested that improvements in the clinical management of severe TBI (according to the GCS, or coma at presentation in the pre-GCS era) have reduced case-fatality rates by more than 50%. However, case-fatality rates appeared to have stagnated over the

Cognitive reserve

Variations in the structural features or functional organisation of the brain (sometimes referred to as brain reserve or cognitive reserve, respectively) that affect susceptibility to age-related or disease-related brain changes, allowing some people to tolerate more of these changes than others and maintain function.
The Lancet Neurology Commission

past 25 years, an impression confirmed by a comparative overview of observational studies, which showed similar rates of unfavourable outcome over the past decades (appendix p 3). Further improvements in care are needed to reduce mortality and to improve outcomes for survivors of TBI.

TBI in specific populations

TBI in children and adolescents

Despite the growth and dissemination of injury-prevention programmes and education campaigns (section 3), TBI remains the leading cause of death in children and adolescents in HICs. In fact, the full scope of the public health crisis of TBI is only now emerging. According to US CDC data, in 2013 there were more than 64000 TBI-related emergency department visits for children aged 14 years or younger. However, this staggering number is likely to be an underestimate: data from large health networks suggest that about 80% of children and adolescents with mild TBI present to primary care physicians and not to hospitals, indicating a real incidence that is 4–5 times higher. CDC data show that US emergency department visits for TBI increased between 2007 and 2013 for the 0–4 year and 5–14 year age groups, rising by 37.8% in the youngest age group (1591.5 cases per 100 000 people), which has the second highest incidence for any age group after adults over 75 years of age.

TBI affects more boys than girls, with a 1.4-times higher incidence in boys less than 10 years old and a 2.2-times higher incidence in boys aged 10 years or older compared with girls. Additional disparities in incidence and outcomes exist in relation to race and ethnicity. For instance, African-American children were at a 40% increased risk of TBI compared with non-Hispanic white children. African-American, Hispanic, and native American children were more likely to experience TBI from violence and have more severe TBI and higher mortality rates than were non-Hispanic white children in the USA.

CDC data indicate that injury causes also vary with age. Falls predominate in the 0–4 year age group, falls and being struck by (or having the head strike) an object are equally common in the 5–14 year age group, and motor vehicle incidents predominate in the 15–24 year cohort. The rates of TBI and its complications in children and adolescents seem to be similar in Europe and the USA, but are higher in other regions, such as China, India, and South America.

A unique aspect of TBI in children is that it includes injuries inflicted by child abuse. In abusive head trauma, children are generally too young—or sometimes too injured—to be reliable historians, and investigations are required to eliminate further risks for the injured child and any other children in the environment, and discover the circumstances surrounding the injury. A comprehensive analysis of data from the past 15 years appeared to show declining rates of fatal abusive head trauma. Nevertheless, recent evidence suggests that abusive trauma is the most common cause of severe TBI in children under 2 years of age. Although some studies have shown poorer outcome in children with abusive head trauma compared with those injured by other mechanisms, this was not confirmed in a recent study.

At a societal level, the effect of childhood TBI is enormous, with burdens on the health-care system, scarce resources for rehabilitation and school systems, and a substantial socioeconomic impact on families (sections 2, 4).

TBI in the elderly

The definition of elderly in the context of TBI is variable: cutoffs in published papers range from 55 to 75 years of age. However, regardless of the cutoff used, older individuals are clearly at a higher risk of TBI and experience more severe consequences than do younger people, even from seemingly mild TBIs. Demographic projections suggest that future rates of TBI among older individuals in LMICs are likely to approach current levels in HICs, and hence the future health-economic and public health burden of TBI is likely to increase dramatically.

People over 65 years of age represent 10% of TBI cases, but account for 50% of TBI-related 10-year mortality risk and have high and increasing rates of TBI-related hospital admissions. The rise in TBI incidence in older individuals is not solely due to an ageing population. Many elderly people remain mobile and semi-independent owing to decreasing morbidity from cardiovascular disease and cancer. They are then at risk of falls, which are the main cause of TBI in this group. Loneliness and depression might also lead to alcohol abuse, which is increasingly being recognised in older individuals and can potentially increase the risk of falls and compromise chances of recovery owing to decreased cognitive reserve. Moreover, increased use of CT imaging might have improved case ascertainment for TBI in older people.

Age is among the strongest outcome predictors in TBI, with mortality and unfavourable outcome increasing continuously with age (appendix p 4). The perception of a universally poor outcome has sometimes led to therapeutic nihilism and less aggressive treatment for older patients with TBI, who experience delayed CT imaging, a lower likelihood of transfer to specialist neurosurgical facilities, and care by more junior medical staff. Treatment-limiting decisions might be taken sooner in older patients. The poor outcome resulting from such suboptimal treatment might fuel the perception of a universally poor outcome has sometimes led to therapeutic nihilism and less aggressive treatment for older patients with TBI, who experience delayed CT imaging, a lower likelihood of transfer to specialist neurosurgical facilities, and care by more junior medical staff. Treatment-limiting decisions might be taken sooner in older patients. The poor outcome resulting from such suboptimal treatment might fuel self-fulfilling prophecies of poor prognosis and reinforce current prejudices. Such nihilism is unjustified: overall, when older patients are treated aggressively and promptly following admission to the intensive care unit (ICU), favourable outcomes are seen in 39% of patients aged 60–69 years. Epidemiological studies will be crucial in
helping to understand the burden of TBI and response to treatment in the elderly population. Moreover, improved epidemiological monitoring in the elderly could help to raise awareness of the risks of head trauma in this group and inform prevention programmes (section 3).

Sports-related TBI

Sports-related concussion is a frequent cause of TBI, and is currently the focus of public debate and controversy, owing to uncommon (but dramatic) clinical presentations such as second-impact syndrome and the association of concussion with later cognitive decline and CTE. In the USA, the CDC estimates that between 1·6 and 3·8 million concussions occur annually. However, this might be a considerable underestimate, as many concussions do not reach medical attention. In the USA, cycling is responsible for the majority of sports-related concussions, according to the American Association of Neurological Surgeons, whereas in New Zealand, rugby (both league and union combined), cycling, and equestrian sports have been linked to the highest rates of sports-related concussion.

A recent systematic review of 13 studies of concussion in 12 sports reported an overall pooled incidence of 0·23 (95% CI 0·19–0·28) per 1000 athlete exposures to sport, with the highest incidences in rugby, ice hockey, and American football. Variations in participation between sports and in definitions of concussion between countries result in inconsistent statistics. Concussion rates vary by age group, sport, and gender, and are generally reported to be higher in competition than in practice. In terms of head injuries per hours of sport, equestrian sports appear to have the highest rate of concussion. In Europe, there is a lack of research on the epidemiology of sports-related injury, across all sports.

Notwithstanding inconsistencies, the reported incidence of sports-related concussion is steadily rising. The CDC reported a 62% increase in sports-related TBI treated in emergency departments between 2001 and 2009, and annual increases of 7–15% have been suggested for concussion rates in collegiate and high-school sports in North America over the past two decades. These concerns are not confined to the USA. For example, the English Rugby Football Union has reported year-on-year increases in concussions in professional rugby since 2003. These trends are generally attributed to increased awareness and reporting of concussion, partly promoted by media attention. Concerns have also been expressed about players becoming progressively heavier and stronger, and more emphasis being placed on the physical element of sport. Nevertheless, the underlying true rate of concussion remains unclear, as the majority of these injuries are not reported, either deliberately or because of lack of awareness. Further efforts to understand and increase awareness of the consequences of sports-related TBI are needed, with improved detection of and response to concussion, to prevent or reduce the effects of such injuries (section 3).

TBI in military conflict situations

Current global conflicts, and the increasing burden of terrorism across the world, have resulted in a steady increase in the number of patients with military and military-type injuries. US data show that TBI is the signature injury of the Iraq and Afghanistan conflicts, accounting for approximately 20–25% of the combat casualties reported in the Joint Theater Trauma Registry. Between January 2010 and August 2016, 352619 TBIs were reported in US service members. Of these, 82% were classified as mild, 9% as moderate, and the remaining 9% as severe or penetrating, or not classifiable (including instances of death in action and inadequate or incomplete documentation). Therefore, as with civilian populations, mild TBI constitutes the largest proportion of TBI in military personnel, and although most individuals with mild TBI return to full duty with no lasting complications, approximately 10% have symptoms that do not resolve.

Overall, combat-related TBI is a substantial cause of morbidity and mortality, and, unlike civilian TBI, often includes blast-related TBI and extracranial polytrauma such as amputation, internal haemorrhage, and burns. Blast as an injury mechanism was until recently largely confined to conflict settings, but has become more relevant in civilian populations owing to an increase in terrorist incidents. Injury mechanisms can be more complex than in non-blast TBI, and experience in the military setting suggests that the clinical course can also be different. Several active research programmes are focused on the differences between blast-related TBI and TBI of other causes. The most comprehensive of these, from the US Department of Defense, includes efforts to understand the epidemiology and to improve the identification, management, and treatment of mild TBI, with protocols for mandatory screening and detailed clinical recommendations.

US data from recent conflicts in Iraq and Afghanistan document the lowest killed-to-wounded ratio in the history of warfare, with many casualties surviving what would previously have been fatal injuries. Although advances in body armour might help to explain increased survival, developments in military medical care have probably made a substantial contribution. A key factor underpinning increased survival is development of an integrated and effective chain of trauma care in conflict settings (section 4). The effect of improvements in care pathways on the burden of TBI might be less impressive than for other types of trauma (section 4), but the lessons learned about the epidemiological and clinical issues can be applied beyond conflict settings and have relevance for improving TBI outcomes in the civilian population.

TBI in offenders

There is evidence for an association between TBI and crime: TBI appears to be a risk factor for criminal behaviour, and a criminal lifestyle might increase the risk...
of TBI. Importantly, there are shared risk factors for TBI and criminal behaviour, including socioeconomic adversity, risk-taking behaviour, and conditions such as attention deficit hyperactivity disorder (ADHD), mental health disorders, and alcohol or drug misuse. In support of these links, a Finnish birth-cohort study showed that a history of a TBI during childhood or adolescence was associated with a 4-times increased risk of having a mental health disorder with coexisting criminality in men. A 35-year, retrospective, total-population study in Sweden showed a substantially increased risk of violent crime in people with TBI: 8·8% of those with TBI had committed violent crime, compared with 3% of population controls (adjusted odds ratio 3·3, 95% CI 3·1–3·5): risk was attenuated when those with TBI were compared with unaffected siblings (2·0, 1·8–2·3). Prevalence of TBI is 3–8 times higher in offender populations than in non-offender groups. In a UK prison study, Williams and colleagues found that 16% of inmates had experienced a moderate-to-severe TBI and 48% had had a mild TBI. About half of young offenders have had loss of consciousness, with repeated injury being common. TBI in offenders is associated with earlier offending, higher levels of reoffending, violence, and suicidality. A neuroimaging study of prisoners in Germany showed that offenders had a significantly higher rate of structural brain abnormalities, and that violent offenders had significantly higher rates compared with non-violent offenders and controls.

There are intricate links between TBI and ADHD: ADHD can be a consequence of TBI, but it is also a risk factor for TBI, and can be complicated by the injury. Since ADHD is common in offender groups, studies of TBI in these populations should consider the contribution of this condition. In a non-TBI study, intervention with medication for ADHD in offenders led to a 30% reduction in criminality, possibly owing to improved impulse control. Screening for and management of TBI in offenders is possible, and specialist services tailored to offenders with TBI, and comorbid mental health and neurodevelopmental disorders, might support changes in behaviour that potentially lead to a reduction in crime.

There is a pressing need for more research to characterise the association between TBI and criminal behaviour in offender populations. In particular, longitudinal studies are needed to understand the increased risks of crime in those with TBI, the causal relations between TBI and criminal behaviour, and the factors that contribute to these risks. Furthermore, studies are needed to characterise imaging abnormalities and neuropsychological impairments associated with TBI in offender populations to understand how brain injury affects behaviour, including risk of reoffending.

Improving epidemiological studies of TBI

TBI is a huge but poorly quantified public health problem. The considerable differences in reported incidence and mortality rates between countries highlight a need for better standardisation of epidemiological studies of TBI, for both administrative purposes and research. Recommendations for improving epidemiological studies—in particular, for population-based incidence and outcome studies—are summarised in the appendix (p 4), and emphasise the need for standardised definitions, methods, and data presentation. Future studies also need to use more standardised methods of data collection, especially for mild TBI, to facilitate pooling of data and comparisons between countries and over time.

We need population-based studies on the prevalence, incidence, and mortality of TBI across the lifespan, particularly in LMICs, to improve the accuracy of estimates of the global impact of TBI. Capture-recapture methods could usefully supplement population-based studies, particularly when resources are limited. More advanced metrics, including YLLs, years of life with disability (YLD), or disability-adjusted life years (DALYs)—a measure of overall disease burden, expressed as the number of years lost due to ill health, disability, or early death—should be used to better quantify the burden of TBI. A simple and cost-efficient approach might be to include a question on TBI in routinely conducted health interviews, such as the European Health Interview Survey, which has a section on self-reported injury in the past 12 months, and could yield insights into incidence and prevalence of TBI in the general population.

Improvements in completeness and quality of epidemiological data are required for the detection of high-risk populations (such as the very young and very old) and identification of key targets for improved prevention and management of TBI (sections 3, 4), to enable development and implementation of policy measures.

Key messages and recommendations

Key messages

(1) Worldwide, TBI is a leading cause of injury-related death and disability, with a devastating impact on patients and their families.

(2) Current epidemiological monitoring is incomplete, especially for mild TBI.

(3) In LMICs, the incidence of TBI due to traffic incidents is increasing, while in HICs, TBI increasingly affects elderly people, mostly due to falls. Methodological variations, however, confound comparisons of epidemiological patterns of TBI between regions, countries, and continents.

(4) TBI might represent an important modifiable risk factor for epilepsy, stroke, and late-life neurodegenerative disease.

Recommendations

(1) Concerted efforts to address this vast global health problem should focus on policies aimed at reducing the burden and impact of TBI, through better prevention,
improved access to care, and promotion of clinical research to improve treatment standards.

(2) Rigorous epidemiological studies are needed to capture the changing patterns of epidemiology and to identify high-risk groups and key targets for improved prevention and management of TBI.

(3) An international consensus is needed on definitions and standardised epidemiological monitoring of TBI to allow accurate measurement of incidence, prevalence, and mortality, and comparison of rates of access to community, hospital, and residential care.

(4) Studies are needed, in children and adults, to better understand links between TBI of all severities and an increased risk of later neurological diseases.

Section 2: Health economics of TBI

TBI has a huge economic impact on affected individuals and families, and on society as a whole. Understanding the health economics of TBI is an important step in efforts to improve efficiency of care and prevention worldwide. However, accurate estimates of TBI costs are scarce for many regions, and there is wide variation in reported costs between available studies. This partly reflects differences in methods used to calculate costs and variations in definitions of direct, indirect, and lifetime costs used in research studies (panel 4).

Understanding of costs associated with TBI can provide insight into the magnitude and scope of the problem and generate the knowledge necessary to anticipate and budget for health-care services needed to prevent, detect, and treat TBI. Accurate cost estimates allow assessment of potential savings that could be made with interventions aimed at reducing the incidence or improving the treatment of TBI. Costs can also be considered to reflect resources used per individual and provide a proxy measure of health-care use. Identification of disparities and inequities in access to and delivery of health care, crucial for the provision of good treatment, allows researchers and decision makers to recognise areas where public health interventions could be beneficial.

In this section, we review available health-economic data on the costs related to TBI and discuss the implications for health-care policy. Furthermore, we suggest directions for future health-economic studies to improve understanding of costs and patterns of health-service use after TBI, which could facilitate decisions on prevention strategies and health-service planning.

Direct and indirect costs of TBI

The economic consequences of TBI for individuals and for society are enormous. TBI-related costs in Europe for 2010 have been estimated at €33 billion (equivalent to about US$49·7 billion in 2017), of which direct costs accounted for 41% and indirect costs accounted for 59%. In the USA, reported aggregated direct and indirect cost estimates ranged from US$60·4 billion (about US$85·6 billion in 2017) in 2000 to US$221 billion (about US$252·2 billion in 2017) in 2009. In the earlier USA study, 15% of the costs were accounted for by lifetime medical costs and 85% by lifetime productivity losses. The data from 2009 showed that 31% of the costs were due to loss in productivity and 62% resulted from intangible costs (lost quality of life). The higher total cost estimates in the later study might be explained by the inclusion of intangible costs. Costs attributable to TBI in Australia in 2008 were estimated to be AUS$8·6 billion (about US$7·9 billion in 2017), of which absence from work or productivity loss due to TBI accounted for 55%.

Lifetime costs of TBI are high, owing to loss of productivity in a substantial number of younger patients, but these long-term costs are not considered in all studies. For example, in Europe, the reported health-service-related and indirect costs for stroke have been estimated to be twice as high as those for TBI, but these comparisons limit reported cost estimates for TBI to the direct and indirect costs for the first year after injury. Such calculations grossly underestimate the actual societal costs of TBI.

The average lifetime cost of TBI in the USA was estimated to be US$396·000 per person (equivalent to about US$555·424 in 2017). In Australia, per-person long-term health-care costs for the first 6 years after injury ranged from AUS$139·427 for moderate TBI (about US$124·703 in 2017) to AUS$226·361 for severe TBI (about US$202·456 in 2017). Many studies, especially from the USA, use the charges payable by individuals or insurers as a proxy for unit prices (ie, the actual costs of provision of care); such cost calculations could underestimate total costs, as many patients with mild TBI do not seek immediate medical care or are misdiagnosed.

The omission of mild TBI from many cost studies might result in an overestimate of the average cost per individual, but an underestimate of the total cost to society. This is partly because accurate population-level data about

Panel 4: Definitions of types of costs used in health-economic studies of traumatic brain injury

Direct costs

All resources consumed (quantified in costs) within the health-care sector as a result of traumatic brain injury (TBI). Direct costs could also include out-of-pocket expenses and resources outside the health-care sector.

Indirect costs

All resources foregone as a result of TBI. Costs included in this category vary by study but most include productivity loss, which arises when people who would otherwise be employed are not able to work or work fewer hours because of their TBI. Indirect costs could also include intangible costs due to TBI, such as those associated with reduced quality of life or time and effort spent by family members on care.

Lifetime costs

Costs incurred over a lifetime to provide services to people with TBI that would not be required in the absence of injury, such as ongoing medical care and community services.
resource use and the health impact of TBI are scarce. The recently completed BIONIC (Brain Injury Outcomes New Zealand In the Community) study was the first to assess the incidence of TBI for all severities across all age groups, in both rural and urban populations. The BIONIC collaborators found that the cost of treating TBI varies greatly, with first-year and lifetime costs per person for mild TBI (calculated at US$3395 and US$4636, respectively) being significantly lower than those for moderate-to-severe TBI (US$21379 and US$36648, respectively).25 Other estimates, based on patients admitted to a rehabilitation facility—approximately AUS$350000 (equivalent to about US$309000 in 2017) over a 10-year period for severe TBI,27 for example—underline the high costs of efforts to promote recovery in survivors, as rehabilitation interventions are often intensive and prolonged. Costs of care in individual patients can be 10 times higher than those for the average patient, and vary with both injury severity and demographic features.27,28 Despite the lower treatment costs of mild TBI for individual cases, the high incidence of mild TBI results in a total treatment cost across patients of nearly 3 times that for moderate-to-severe TBI.26 Accurate estimates of total global costs of TBI are lacking, but extrapolation from estimates of new mild (52–56 million) and moderate-to-severe (2.2–3.6 million) TBIs per year worldwide from the BIONIC study25 suggests that the global economic burden of TBI could range from US$362 billion to US$445 billion in 2017, which equates to 0.5% of the annual global output, estimated at US$75.6 trillion.1 The actual costs could be even higher, as intangible costs, such as those related to loss of quality of life or the time and effort spent by family members on care, are not taken into account in these estimates.

Although all studies attest to the high societal costs of TBI, in terms of both medical costs and lost productivity, the variation in estimates is striking. Some differences are probably real; however, rigorous comparison of these figures is impossible, since the source data are of relatively poor quality, calculations involve several assumptions and variable methods, inflation-related changes in exchange rates are usually ignored, and the precise cost items included in estimates (and the duration of the post-injury period to which they refer) vary substantially, or are simply not specified (appendix p 5).

Other indirect consequences, which have rarely (if ever) been taken into account in calculating TBI-related costs, include caregiver time and expense, caregivers’ working ability and health, increased psychiatric morbidity and injury risk among TBI survivors, and increased likelihood of alienation, as well as costs related to long-term complications of TBI, including those of dementia care.31,32 Taken together, these limitations underline the need to interpret with caution current estimates of health-service use and costs of services. As with other epidemiological data, there is a pressing need to ensure uniformity of reporting of health-economic data (section 1).

Implications for health-care policy

The huge economic burden of TBI worldwide necessitates improved prevention and treatment strategies from a health-economic perspective. However, accurate data on costs as a proxy measure of health-care use are lacking. Current estimates of the range of total costs are incomplete for both mild and severe TBI. For patients with severe TBI, we need better insight into the long-term costs of specialised hospital and rehabilitation care. There is a crucial need to couple improved epidemiological and economic data collection to rigorous analysis of health-care and lifetime costs of TBI so that we can identify patient groups with high costs of care and deficiencies in access to services, and make rational decisions about allocation of health-care resources. Models for predicting lifetime costs for individual patients are now emerging, and might also be useful in assigning costs to the care needs of survivors of TBI.33

Data on total costs of TBI, and on indirect costs in particular, are limited. We need improved understanding of all types of indirect costs, especially the negative effects of TBI on work performance and resulting production losses, which dominate the economic burden of TBI. Future research should incorporate the productivity costs in cost assessments, as this provides important input for policy decisions and enables priority setting on the basis of the total direct and indirect expenses due to injuries. These data are also vital to calculate the cost-effectiveness of programmes or treatments used to improve the chances of returning to work in working-age survivors of TBI.

Substantial cost savings could be achieved by preventing TBI. At the level of individuals, cost savings might be more relevant at the severe end of the spectrum, but the large number of patients with mild TBI suggests that effective prevention strategies to reduce incidence of mild injuries could be more beneficial at a societal level. Realisation of such cost savings will require investment in prevention (section 3). As well as increased governmental investment, additional funds could be made available by following the example set by Italy, where a portion of the fees for traffic law violations must be spent on traffic incident prevention.30

Key messages and recommendations

Key messages
(1) TBI results in substantial health-care and societal costs.
(2) High-quality data on the health economics of TBI are not available for many regions and countries, especially for lifetime costs.
(3) Methodological variations confound comparisons of the health-economic impact of TBI across regions, countries, and continents.

Recommendations
(1) More effective strategies for TBI prevention are urgently needed, and could deliver cost savings that help to fund research and improved access to health care for TBI.
Section 3: Prevention of TBI

TBI is, to a great extent, preventable, and the benefits for society of decreasing its occurrence are far-reaching: TBI prevention saves lives, reduces prevalence of disabilities, and saves costs inside and outside the health-care system. Although TBI prevention strategies (such as those aimed at road traffic safety) in some regions have been remarkably successful, these achievements are not universal. Increased use of motor vehicles in LMICs, coupled with an inadequate infrastructure and insufficient adoption of safety measures, has resulted in substantial increases in the burden of TBI. Successes achieved in prevention of TBI from road traffic incidents in HICs need to be replicated in LMICs. Furthermore, steps need to be taken to address increases in TBI in other demographic contexts, including specific measures to reduce the incidence of TBI caused by falls in the elderly, and to prevent brain damage in children and in amateur and professional athletes.

Prevention measures that target injury occurrence, whether primary or secondary measures, should be informed by knowledge of TBI epidemiology and causes, and identification of risk groups. Primary prevention is directed at prevention of injury occurrence, whereas secondary prevention aims to reduce the occurrence of TBI or limit its severity if an injury happens.

Primary and secondary approaches can be effective in isolation, but use of both prevention strategies is needed to maximise benefits. Prevention initiatives can be applied at a population level—eg, with legislation, improvements in infrastructure, vehicle safety design, trauma care, or workplace safety measures. Alternatively, prevention measures can focus on high-risk subgroups. Examples include the targeting of drivers and cyclists to prevent alcohol-impaired driving, speeding, and distracted driving; promotion of seat belt, child restraint, and helmet use; a focus on elderly people living alone and at risk of falls; and strategies aimed at children at risk of abuse. Finally, it might also be possible to specifically target individuals to address their patterns of risk-taking behaviour.

Irrespective of the target population, information campaigns should employ a range of measures to raise awareness of key issues in prevention and care for TBI. The potential of broad education and awareness campaigns, also using social media, is exemplified by the success of the ThinkFirst National Injury Prevention Foundation, established in the USA in 1990.

In this section, we discuss approaches to reduce the occurrence and impact of TBI, focusing on prevention of TBI from road traffic incidents and sports, as well as TBI in children and adolescents and the elderly.

Prevention of TBI from road traffic incidents

Globally, TBI remains predominantly a disease of the young, with road traffic incidents being the major cause in LMICs, where vulnerable road users (pedestrians and cyclists) are particularly at risk. Even though LMICs have only half of the world’s vehicles, 90% of the world’s road fatalities occur in these regions, a substantial proportion of which are preventable.

Reduction of traffic-related injuries is the focus of the United Nations Decade of Action for Road Safety (2011–2020), which aims to halve the 1·3 million traffic-related deaths that occur each year by 2020 through improved road-safety management, enhanced road and vehicle safety, better-informed road users, and an improved post-crash response. These improvements are relevant to TBI, since it is a major cause of all injury-related deaths (section 1). A recent World Health Organization (WHO) report on road safety provides specific recommendations for improving road safety, based on interventions with proven efficacy. Reduced speed limits have played a crucial part in decreasing crash incidence and injury severity. A systematic review of studies from HICs confirmed that enforcement of traffic rules decreases road-user deaths. Non-legislative approaches are equally relevant, and include developing safer roadway infrastructure (separating pedestrians and cyclists from motorised vehicles), introducing traffic-calming measures, and implementing vehicle and safety-equipment standards. Other effective population-wide strategies for preventing road crashes, injuries, and fatalities include the installation of red-light cameras and street lighting.

Secondary prevention strategies include use of protective head gear and car safety measures. Mandatory helmet use has decreased the number and severity of head injuries among both motorcycle and bicycle users. In Taiwan, introduction of the motorcycle helmet law in 1997 reduced motorcycle-related head injuries by 33%, and injuries that did occur were less severe and associated with shorter hospital stays. Despite strong evidence that helmets reduce the severity of injuries from motorcycle crashes and increase the likelihood of survival, helmet laws are not universally implemented, even within the USA.

In HICs, recent attention has focused on the risks incurred by distracted drivers. The likelihood of a safety-critical event occurring while driving has been reported to be 6 times higher for drivers dialling a cell phone and 23 times higher for those texting. Although campaigns aimed at influencing drivers’ behaviour remain relevant, technological solutions should also be considered. In particular, there have been suggestions to develop smart solutions to recognise and block non-hands-free cell phone use while driving.
Prevention of sports-related TBI

Ongoing research aims to determine the long-term consequences of single concussive injuries. However, increasing evidence indicates that multiple concussive and subconcussive impacts can have cumulative effects, including more severe symptoms and more prolonged recovery than after a single injury of similar severity, as well as increased vulnerability to brain injury and heightened risk of any subsequent injury.204,205 In children and adolescents, there are additional concerns about the cumulative effects of multiple concussions on brain development and learning, and the consequent cognitive and behavioural sequelae.206 Children and young adults are also at increased risk of second-impact syndrome.207,208 These emerging concerns underscore the importance of immediately removing anyone from play when there is any suspicion of a possible TBI. This recommendation is highlighted in training programmes for coaches and parents but, unfortunately, is not always applied in professional sports. During the FIFA (Fédération Internationale de Football Association) World Cup in 2014, there were several incidents of apparent concussion in players who were allowed to continue play, which led to a change in the FIFA Medical Committee’s protocol, whereby a team doctor now has the responsibility and sole authority to make an assessment about suspected concussion and decisions about return to play.209 We argue that professional sports organisations should be obliged to remove any player with a suspected TBI from play immediately, thus setting an example for amateur athletes and, in particular, young players. Such decisions should not be taken by interested parties (eg, coaches), but rather by a neutral party such as an independent medic or, if not available, the referee. Various international efforts have been initiated to develop, refine, and implement rational guidance for players, parents, and coaches about the time that needs to be spent away from training and contact sport following a concussion.210,211 However, further refinement in diagnosis is needed, as is guidance on action required when concussion is reliably diagnosed.212,213

Prevention of TBI in children and adolescents

The topic of TBI in children and adolescents has substantial emotional, legal, and financial ramifications. Children and adolescents are at particularly high risk of accidental TBI, and such injuries in this group can have substantial effects on families and communities worldwide. Most prevention strategies outlined for road traffic incidents and for sports injuries—particularly those related to helmet laws for bicycles, motorcycles, and other motorised vehicles, and to concussion detection and prevention from sports injuries—apply to both children and adults. However, two aspects of injury prevention are unique to children: the use of car seats and the concept of multi-agency safeguarding for children at risk of abuse, with infants being the most vulnerable.216 Community-based interventions to promote the use of child car-seat restraints can reduce the risk of motor vehicle occupant injuries by 33–55%.217 In the USA and other areas of the world, local laws state that children should be restrained in car seats while the motor vehicle is in motion. For example, in Pennsylvania, USA, all children under 8 years of age travelling by car are required to be in a child-restraint system, with children under the age of 2 years in rear-facing seats. Furthermore, the law mandates the use of seat belts for children aged 8–18 years. These state laws218 are broadly replicated in the national best practice recommendations of the US Preventive Services Task Force.219 Similar laws or guidance exist in many other countries (eg, the EU, UK, Australia)220–222 however, such regulations are not universal, and even when in place, are inconsistently applied.223

Child abuse or non-accidental trauma has become more widely recognised as an important cause of TBI in infants and children. Since awareness of child abuse has increased and family risk factors have been elucidated, local programmes have been developed in the USA and other countries to educate parents about the dangers and long-term effects of brain injury, and to provide caregiver relief and advice on coping skills for stress. In the USA, the concept of safe havens for children at risk of abuse has been advanced,224 whereby parents who fear they might harm their baby or child can leave the child without risk of prosecution. These safe havens are often paediatric hospitals or family refuge shelters that provide emergency medical care for the child and assume protective custody until the appropriate state authorities can find a more definitive or optimum placement. Whether these legal remedies have reduced the incidence of TBI in these children is not clear, and the possibilities of furthering the cycle of abuse in alternative placements has not been studied.225 More research is therefore needed to understand the effectiveness of this and other potential interventions, along with efforts to educate caregivers and others involved in the lives of children and adolescents, to prevent TBI in this vulnerable group.

Prevention of TBI in the elderly

Prevention strategies need to take account of changing epidemiological patterns, which show increases in fall-related TBI in older individuals (section 1).211,212,213 Frailty elderly people are more likely to fall, more likely to suffer a TBI when a fall occurs, and more likely to suffer long-term adverse effects even from a seemingly mild TBI.224 There is a clear need, therefore, to address causal risk factors and to explore preventive strategies that address the association between frailty and vulnerability to TBI through falls. Assessment of frailty now involves the use of validated tools, and can be implemented as part of health policy.225 Such assessment is clearly important as a primary TBI prevention strategy. Detection of frailty can trigger assessment and modification of the home environment (including the provision of safety rails for stairs and
steps), and prompt critical evaluation of the risk–benefit ratio of drugs that increase the likelihood of an adverse impact of falls (eg, sedative drugs and medications associated with postural hypotension, and antiplatelet drugs). Frailty assessments (and subsequent interventions) were originally the domain of geriatricians rather than primary care physicians, and initial trials focused on reducing falls and fall-related injuries in acute hospital settings. However, emerging data suggest that these interventions can be more usefully applied in primary care. An example is the Stopping Elderly Accidents, Deaths, and Injuries initiative of the CDC. Risk assessment for falls, followed by implementation of an individualised management plan, has been shown to reduce falls by 24%, highlighting the crucial importance of fall prevention in the elderly as a highly effective TBI-preventive approach.

Key messages and recommendations

Key messages

1. TBI is, to a great extent, preventable, and societies can make considerable gains by decreasing its occurrence.
2. In LMICs, the incidence of TBIs due to traffic incidents is increasing.
3. Second or subsequent concussions that occur before recovery from an initial concussion can be associated with more severe symptoms and more prolonged recovery than a single injury of similar severity.
4. Children and adolescents are at particularly high risk of accidental TBI.
5. Non-accidental injury is an increasingly recognised cause of TBI in infants and children, and although some policies to reduce this risk are currently in place, their effect is uncertain.
6. In HICs, epidemiological patterns of TBI are changing, with an increase in elderly patients with TBI caused by falls.

Recommendations

1. Policies aimed at reducing the burden of TBI should focus on awareness campaigns and prevention of TBI in general, and on strategies specifically to target high-risk groups.
2. The WHO recommendations on road safety need to be implemented in all countries.
3. Any risk of an early second injury after even a mild TBI should be avoided; professional sporting organisations should set an example for children and amateur athletes by immediately removing from play anyone with a suspected concussion.
4. Prevention programmes should target contexts in which TBI in children and adolescents typically occur—eg, promotion of better car safety worldwide, promotion of helmet use by bicycle and motorcycle users and in sports such as ice hockey, and education for coaches and parents of children who participate in sporting activities are needed.
5. Further research is needed to evaluate current initiatives and to explore new options for reducing TBI due to child abuse.
6. Prevention programmes and health-care delivery need to be tailored to the changing epidemiological patterns of TBI, and specifically to prevention of falls in the elderly.

Section 4: Systems of care for TBI

In an ideal world, all patients would have access to optimum care for TBI, meeting standards of best practice, with continuity of care guaranteed from the prehospital phase to the postacute phase. In reality, systems of care for patients with TBI show substantial variation between and within countries, with disconnects in the trauma chain, particularly between acute and postacute care. Understanding such variation is crucial: practice variations influence TBI outcomes and health-care costs (section 2), and broad implementation of best practices and guidelines to improve care pathways has great potential for improving cost-effectiveness and overall outcome after TBI.

The spectrum of clinical care for TBI extends from immediate on-site emergency care (lasting minutes to hours) to long-term postacute care (extending for years or even a lifetime). This care pathway includes several decision points with competing options for care (figure 5). Appropriate choices can enable delivery of high-quality, cost-effective care, whereas poor choices incur the risk of disrupting continuity and reducing quality of care. Variations in systems of care are largely driven by differences in resource availability, local practice, financial frameworks, and physician preferences, in addition to a general lack of strong evidence to support guideline recommendations.

In this section, we discuss the current structure and practice of health care for patients with TBI, focusing on variations in systems of care in the prehospital, acute, and postacute phases, and examine the cost-effectiveness of interventions. We also consider specific challenges in LMICs, identifying the barriers to and opportunities for implementation of improved systems of care and best practice.

Prehospital care for TBI

Prehospital care marks the start of the chain of trauma care and comprises various components: first responders, dispatch systems, basic response, mobile medical teams, helicopter emergency medical services, and hospital choice. Together, they form the essential bridge to definitive care. The concept of the initial post-injury golden hour is especially pertinent to TBI. Suboptimal care in the prehospital phase could result in a progressive cascade of events with detrimental effects throughout the subsequent disease course.

Lack of adequate prehospital care is a particular problem in LMICs (panels 3, 5, 6, 7). The BEST-TRIP (Benchmark for more on the Stopping Elderly Accidents, Deaths, and Injuries initiative see https://www.cdc.gov/steadi/
Evidence from South American Trials: Treatment of Intracranial Pressure) trial,238 conducted in Bolivia and Ecuador, showed that more than half of patients with severe TBI were brought to hospital in vehicles other than ambulances, and long transit times were reported. In HICs, large variations exist in the structure and processes of prehospital care.243–247 Several specific questions remain to be answered—eg, whether it is beneficial to spend time stabilising patients at the scene of injury before transfer or to transfer them to hospital as rapidly as possible (so-called stay-and-play vs scoop-and-run). Whether transfer teams should include physicians, and when the use of helicopters becomes clinically beneficial and cost-effective also remain unclear. A survey conducted in 71 neurotrauma centres in Europe revealed striking differences in dispatch systems (23% dynamic vs 73% selective), in basic response (58% advanced life support vs 41% basic life support), and with regard to policy at the scene (35% scoop-and-run vs 51% stay-and-play; van den Brande R, Antwerp University Hospital, Edegem, Belgium, personal communication). Uncertainty exists about best practice and whether this should depend on local settings (eg, rural or urban) and distances between the injury location and the hospital (general or specialist) offering care.

These uncertainties about the delivery of prehospital care for TBI, and the involvement of multiple emergency providers (paramedic, fire, and police services), highlight the need for clear and widely accepted practice recommendations for prehospital trauma care. Evidence and experience from settings in which risk of TBI is high, such as military settings, might support the development of recommendations more broadly. As with civilian TBI, a key consideration in military settings is the need for an integrated and effective chain of care throughout the casualty care continuum, including battlefield first-responder care, tactical field and evacuation care, and subsequent care across the global military care system.157,248 While developments in military medical care in the past decade have clearly made a substantial contribution to improved overall survival rates for military personnel injured in conflict areas,156,157 advances in the treatment of TBI, especially on the battlefield and in the postacute phase, have been less impressive.157,249

In more severely injured patients, potential challenges in this context include triaging intracranial bleeds and the stabilisation or treatment of polytrauma accompanying TBI at the point of injury and during transportation to specialist trauma centres that can provide the advanced multidisciplinary expertise needed for optimum management of TBI.159 Strategies to address these issues include ambitious plans to bring advanced care closer to the injury location to ensure rapid intervention within the golden hour.119 These advances are important not only for military TBI (and trauma in general), but also for civilian TBI, since the technologies and systems developed and refined through these initiatives can inform civilian TBI care.159

Hospital care for TBI

Controversy exists about whether patients with more severe TBI should be transported to the nearest hospital or taken directly to a specialist trauma centre with specialist care facilities that should encompass neurosurgery, neurocritical care, neuroradiology, and
neurorehabilitation. This controversy is partly due to challenges in reliably diagnosing and categorising the severity of TBI at the scene of injury. Retrospective analyses of administrative and registry databases suggest that transfer from non-specialist hospital settings to specialist trauma centres, and possibly to high-volume centres, can reduce mortality and improve functional outcome and cost-effectiveness. Additionally, many studies suggest that care in specialist centres that practise specific interventions (eg, physiotherapy, inpatient rehabilitation) are impossible in HICs, where their availability is standard, but are feasible and ethical in LMICs. When appropriate decisions are taken at each step in the care pathway and the links in the trauma chain remain connected, high-quality care with positive outcomes can be achieved (panel 6). Access and continuity of care should, however, be structurally assured, and not dependent on chance or socioeconomic privilege.

Panel 5: Challenges for traumatic brain injury care in Latin America

Although intensive care unit (ICU) management in Latin America often meets high standards of care despite resource and funding limitations, such facilities are not universally available,210 and prehospital and postacute care are underdeveloped. A total of 55% of patients with traumatic brain injury (TBI) arrive at hospital in vehicles other than ambulances,210 and ambulance services generally provide only transportation without major resuscitation interventions.

In the post-ICU phase, nurse-to-patient ratios are very low, much routine care is left to families, and rehabilitation services are largely unavailable. In a recent clinical trial, none of the 524 study participants received rehabilitation care.213 Although the risk-adjusted ICU death rate is similar to that for high-income countries (HICs) at 14 days, mortality after ICU discharge is 3 times higher.213 Since post-ICU support does not match the high level of ICU care, the benefits on long-term outcome are compromised. These deficiencies could be addressed not only through increased resource allocation, but also by implementing change at the systems and policy levels to improve TBI outcomes in low-income and middle-income countries (LMICs). Prospective trials of specific interventions (eg, physiotherapy, inpatient rehabilitation) are impossible in HICs, where their availability is standard, but are feasible and ethical in LMICs. When appropriate decisions are taken at each step in the care pathway and the links in the trauma chain remain connected, high-quality care with positive outcomes can be achieved (panel 6). Access and continuity of care should, however, be structurally assured, and not dependent on chance or socioeconomic privilege.

Panel 6: When all the pieces fall into place—a patient testimony

In 1988, at the age of 12 years, Laura E Gonzalez-Lara fell down an orchestra pit and suffered a traumatic brain injury (TBI) as she took part in a concert in a small town in Mexico. In the following patient testimony (abridged and edited), Gonzalez-Lara describes what is possible when high-quality, joined-up acute and postacute care are made available, even after a delay in the identification of TBI. At present, such care is inconsistently available to patients in low-income and middle-income countries. Gonzalez-Lara benefited from the support of her parents, both physicians, and extended family. For the full testimony, see appendix p 6.

The injury, hospital presentation, and admission

During the fall, I fractured my skull, causing a tear in one of the blood vessels overlying the brain. At the time, I only complained of a headache. We went through with the concert, though I was feeling short of breath by then and felt the stage lights were too bright: I could not actually play the recorder and only pretended by moving my fingers. Later, as we were getting on the bus, I felt nauseous and vomited. It was on the bus where I finally lost consciousness. Back in my hometown of Puebla, my mother immediately took me to the local university hospital where she was an attending physician. By the time I arrived, my Glasgow Coma Scale score was estimated to be around 7. I benefited from the combined experience of two neurosurgeons to evacuate the haemorrhage roughly 5 h after the fall. Next morning, I was transferred to the best intensive care unit in the city by ambulance.

Postacute care and rehabilitation

Before the week was over, a physiatrist prescribed exercises for my parents to do with me. By the end of the week, I was able to walk and move my right arm. I was released from the hospital a week and a day after the fall to the care of my parents at home. My physiatrist followed up regularly during the first month and adjusted exercises as needed. I had absence seizures and was on anticonvulsant medications until I was around 21 years old. I had regular blood work, electroencephalograms (EEGs), and follow-ups with neurologists and neurosurgeons to make sure everything was under control. The other sequela that lingered was a short-term memory impairment. I continued to work on fine motor control for some time; after several months, I was playing the recorder and the flute again and even rejoined the orchestra.
needed to guide health policy and direct investment to close the gaps in TBI care in China.

Care for patients with traumatic brain injury (TBI) in China is coordinated primarily by neurosurgeons. Progress of Chinese neurosurgery, first founded with Russian cooperation in the 1950s, was completely halted during the Cultural Revolution from 1966 to 1976. Since then, the implementation of modern imaging and monitoring equipment has advanced TBI care. This process has been enhanced by periods of training for Chinese neurosurgical trainees in Europe and North America. Improved systems for prehospital management and transfer to nearby (level I or level II) trauma hospitals have gradually been implemented. The 120 free-call emergency telephone system has been set up in most areas of the country to facilitate rapid response and quick transportation.

In the past decade, the rapid economic growth in China has been accompanied by substantial advances in the prevention and care of patients with TBI. In addition to improved systems for prehospital management, specific gains have been achieved through legislation on alcohol and driving, increased access to computed tomography (CT) scanners, wider availability of neurosurgical services out of hours and at weekends, and increased access to neurointensive care. Teaching programmes and other implementation strategies have increased awareness of the importance of guideline-based management of TBI. Chinese TBI guidelines have been issued for management, drug treatment, intracranial pressure (ICP) monitoring, and use of decompressive craniectomy.239–242 Catheters for ICP monitoring, however, still need to be paid for by patients’ families, resulting in a low rate (24–5%) of ICP monitoring for severe TBI in China.49 International collaborations are increasingly being established, facilitating integration of Chinese research into the international community. Comparative analyses that emerge from such collaborations provide cause for optimism: mortality and unfavourable outcome after severe TBI (Glasgow Coma Scale scores of 3–8) in specialised centres are 22% and 50%, respectively,69 which compare favourably with reported rates in high-income countries.102

Nevertheless, despite these advances, long transport times from the scene of accident to hospital are common because of large distances or major traffic jams in most Chinese cities (very few patients with severe TBI are transported to hospital by helicopter or medical airplanes). Further challenges include incomplete cost coverage, as well as shortages of trained neurosurgeons and limited access to specialist care, especially in the western regions of China and outside large cities. Moreover, the implementation of evidence-based management across China still has a long way to go. Despite efforts towards standardisation, use of treatments without proven therapeutic effects, such as neuroprotective agents, is common, and many neurosurgeons in China still treat patients with TBI according to their personal experience. Increased awareness of these challenges is needed to guide health policy and direct investment to close the gaps in TBI care in China.

Postacute care for TBI

For the postacute phase, there are great disparities in systems of care and patient management between countries, within countries, between institutions, and even from patient to patient within centres of care. A common disconnect between acute and rehabilitation services further compounds these problems. Inadequate access to rehabilitation services can slow or complicate recovery, increasing the burden of care, and patients who experience discontinuities in care have poorer functional outcomes than do those for whom the chain of rehabilitation is continuous.203

A substantial proportion of people with severe TBI regain functional independence between and 5 years after injury,219,271 but this depends on provision of specialised neurorehabilitation.215 In practice, many patients (up to 55%) are discharged home or referred to a non-specialist facility after acute care—often without any referral to rehabilitation therapy.215,271 This raises questions about equity of access to health care, which should be high on the policy agenda.

Cost-effectiveness of systems-level management strategies

Although the clinical benefit of care for patients with severe TBI in specialist trauma centres has reasonably wide acceptance, formal assessments of the cost-effectiveness of such strategies are scarce. The RAIN study suggested that transfer to specialist trauma centres was cost-effective, even when neurosurgical intervention was not indicated.204 An analysis from the UK National Institute for Health and Care Excellence (NICE) found that adoption of algorithms for the selection of patients with TBI for CT imaging of the head and spine, incorporated into NICE guidelines for TBI management, was cost-effective.262 However, a recent systematic review showed that evidence of economic benefit was available for only a minority of interventions for TBI, and much of the existing evidence was of poor quality.273 Panel 8 summarizes interventions for which cost-effectiveness data are available.

With regard to the cost-effectiveness of rehabilitation interventions for TBI, a US National Institutes of Health (NIH) consensus statement in 1998 noted a scarcity of quality publications on this topic and made recommendations to address evidence gaps. There has been little progress since then. Some organisational
approaches, such as the appointment of a case manager to facilitate rehabilitation access, have face validity and are highly valued in anecdotal accounts from patients and families, but there has been little formal evaluation of cost-effectiveness.284 By contrast, a recent decision-tree analysis of rehabilitation for TBI concluded that, compared with a broken chain of care, adopting a more integrated approach yielded a clinically relevant decrease in disability, while saving more than US$4000 per patient.285

Good data on cost-effectiveness of systems of care and interventions for TBI are crucial for planning resource allocation and guiding care pathways. Such data need to be viewed in relation to local case-mix, resource availability, and cultural contexts. Thus, patients with mild and severe TBI will have different rehabilitation needs, and survivors who have the support of extended family might have different rehabilitation needs compared with those who do not. Different treatment recommendations might apply to different subgroups, and cost-effectiveness models should be developed separately for each subgroup. Sensitivity analyses are essential when cost-effectiveness assessments are undertaken in potentially heterogeneous groups.

Specific challenges in low-income and middle-income countries
About 90% of trauma-related deaths occur in LMICs.185 DALYs due to injury progressively rise with decreasing national income levels.286 Moreover, the relative proportion of TBI in injury cases is greater283 and the odds of dying as a result of TBI in injury cases is greater283 and the odds of dying as a result of TBI are more than doubled in low-income countries.284 A broader analysis of surgical care indicates that preventive deaths occur where over 90% of all global health in developing countries, than 10% of worldwide health being attributable to road traffic incidents to 10% by developing a pan-Indian trauma care network, where designated basic (level III) trauma centres, which have facilities and personnel for resuscitation and onward transfer, are available roughly every 100 km. Emergency neurosurgical interventions would take place in more specialised (level II) trauma centres, available roughly every 250 km on key national highways, and could in some cases be done by general surgeons with some neurosurgical training, thus increasing access to emergency neurosurgery within the limitations of existing resources. Other countries also need to develop their own health-care strategies in the context of local priorities and resources.

Current challenges and future goals
Management of patients with TBI is complex and requires appropriate expertise, organisation, and coordination. Timely interventions delivered by well coordinated multidisciplinary teams of experts will increase the opportunities for optimising outcome. However, there are wide variations in systems of care throughout the trauma chain, and evidence for best practice to inform guidelines is lacking, especially for prehospital and postacute care. Therefore, there is a pressing need for new evidence to support practice recommendations, but in the absence of robust evidence, expert consensus-based recommendations are preferable to no recommendations (section 9). The

Panel 8: Cost-effectiveness of interventions for traumatic brain injury

- Selective secondary transfer to specialist trauma centres for patients who present with a Glasgow Coma Scale score of less than 9 at the injury scene: could save £20 000 per quality-adjusted life-year* (QALY) gained.279
- Management of patients with traumatic brain injury (TBI) in dedicated specialist trauma centres: could save £14 000 per QALY gained.285
- Early transfer of patients with TBI to specialist trauma centres even in the absence of need for definitive neurosurgery: could save £11 000 per QALY gained.285
- Liberal use of computed tomography (CT) scanning in children and adults with suspected mild TBI on the basis of a high-sensitivity decision rule: could save costs and gain QALYs.185
- Selective CT scanning of adults with mild TBI on the basis of the Scandinavian Neurotrauma Committee guidelines, with addition of the S100 astroglial calcium-binding protein B (S100B) biomarker: could save up to £71 per patient if guidelines are strictly followed.284
- Management of patients with severe TBI according to the Brain Trauma Foundation guidelines: implementation across the USA could yield societal savings of more than US$1 billion.178
- Early initiation of continuous chain of rehabilitation care: could save more than US$4000 per patient.285

Cost-effectiveness analyses are not available for many TBI interventions, and for those that are available, the evidence is mainly of poor quality. "One QALY corresponds to a year spent in perfect health."
wide variations in systems of care lend themselves to novel approaches such as comparative effectiveness research (CER; section 9) to determine best practice. High-quality cost-effectiveness studies of TBI interventions are also warranted to establish the optimum systems of care and to improve access to acute and postacute care in particular.

With regard to hospital care, the cumulative evidence strongly suggests that patients with more severe TBI benefit from transfer to specialist trauma facilities, irrespective of whether or not they need neurosurgical intervention. Implementation of such a policy is not simple, and requires adequate infrastructure and clear communication. Crucially, high-quality practice recommendations to support such initiatives need to reach and influence key clinical stakeholders. The creation of a network of major trauma services in the UK, for example, along with the clear national guidelines for TBI triage, has increased compliance with current best practice and improved outcomes. However, the available infrastructure (eg, number of beds in trauma centres) could make full compliance with guidelines difficult. Success of any strategy will therefore depend not only on effective knowledge transfer to clinical practitioners (section 9), but also on allocation of adequate resources to make changes in practice possible.

The rigorous assessment of needs and the articulation of effective policies are particularly relevant to LMICs. Some LMICs are moving towards models of care delivery that, although ambitious by recent standards, adopt pragmatic approaches to specialist care, such as the policy initiatives to reduce road traffic incidents and improve emergency trauma care in India. The challenge in these settings is to allocate new resources in ways that best serve local needs and health-care systems, rather than using frameworks developed for the health economies of HICs.

Key messages and recommendations

Key messages

(1) Access to health care is often inconsistent between centres, regions, and countries, especially for acute and postacute care.
(2) Substantial variation exists in systems and quality of care for TBI between centres, regions, and countries.
(3) For optimum care, patients should be moved along a continuous chain of trauma care, from prehospital through to postacute care, with excellent communication between caregivers.
(4) Centres with higher caseloads and specialised facilities have better outcomes for patients with severe TBI than do smaller centres.
(5) TBI and challenges of TBI care in LMICs are different from those seen in HICs.

Recommendations

(1) Health-care policies should aim to improve access to acute and postacute care to reduce the effects of TBI on patients, families, and society.

(2) For systems or interventions for which best practice is reasonably well defined, such approaches should be used as a treatment standard to improve quality of care, and thus patient outcomes and cost-effectiveness of TBI care. In cases for which best practice is not defined, measures to identify best practice are needed.
(3) Measures to improve systems of care for patients with TBI and ensure continuity of care—through urgent and acute care, rehabilitation, and community reintegration—should be high on the policy agenda.
(4) Incentives need to be implemented to stimulate transfer of adult and paediatric patients with severe TBI to specialist centres.
(5) Solutions for improving TBI care and outcomes in LMICs should be tailored to local needs and resource availability, rather than replicating strategies in HICs.

Section 5: Clinical management of TBI

Management of TBI is currently based on a combination of medical and surgical strategies, and, ideally, rehabilitation to promote recovery and social reintegration to address the longer-term complications of TBI. However, many RCTs of interventions for TBI have not shown beneficial effects, or have produced results that cannot be generalised to the wider population of patients with TBI. Therefore, when guidelines are available, they are often based on weak evidence, supplemented by expert consensus or local protocols (section 9).

Clinical management in the ICU has evolved over the past two decades towards standardised approaches. The international guidelines that underpin these approaches are based on evidence from selected patient groups or on targets derived from population averages, which might not apply to all patients. Although efforts to develop evidence-based guidelines for routine use in the ICU are a step in the right direction, this one-size-fits-all approach ignores the complex clinical and mechanistic heterogeneity of TBI.

International guidelines for the surgical treatment of TBI are not supported by strong evidence, and are implemented inconsistently across geographical regions. Furthermore, there is considerable uncertainty and debate about which subgroups of patients might benefit most from some types of surgery and the optimum timing of surgery. The decision to operate might be influenced by local policy or the surgeon’s experience, and also depends on other factors, such as alternative medical options, expected outcome, and patient and family preferences.

Evidence-based guidelines are not available for most rehabilitation interventions. Even when there is recognised best practice, this is inconsistently implemented between centres, and often does not fully account for the diversity of disability after TBI, which warrants individualised application of robust recommendations.

In this section, we consider the challenges in medical, surgical, and rehabilitation management of TBI, and
emphasise the need for more robust evidence to underpin guidelines. Such guidelines should support a flexible approach that enables targeting of treatment based on improved understanding of individual pathophysiology and clinical needs.

**Intensive care management of severe TBI**

Before transfer to the ICU, the priorities for initial hospital care are stabilisation of the patient, and rapid detection and emergency surgical treatment of intracranial bleeding (see below). In the ICU, current guidelines for the medical management of TBI emphasise prevention of second insults, such as hypoxia and hypotension, and, for patients with severe TBI, optimisation of cardiorespiratory physiology, control of ICP, and maintenance of cerebral perfusion pressure (CPP). Initial ICU management comprises a range of medical approaches to attain these targets, including sedation, hyperventilation (to reduce brain oedema), limited hyperventilation (to reduce intracranial volume through hypocapnic cerebral vasodilation without causing ischaemia), drainage of cerebrospinal fluid, and varying degrees of temperature control (ranging from meticulous control of normothermia to induced hypothermia). Aggressive cooling (to core temperatures of 32–34°C), deep sedation (to achieve deep metabolic suppression as evidenced by a near-isoelectric electroencephalogram [EEG]), more intensive hyperventilation, and decompressive craniectomy (removal of a portion of the skull to accommodate brain swelling) are often classified as third-tier therapies and reserved for patients with refractory ICP elevation. Such stratification, with prioritisation of more conservative medical approaches, is rational, since none of these treatments is risk-free and they can be associated with a worse outcome. However, some clinical trials of these interventions have not replicated common clinical settings or timings of interventions in clinical practice.

Current treatment approaches aim to maintain single target values (or target ranges) for ICP and CPP, derived from analyses in populations of patients with TBI. Evidence in support of this single-goal-directed approach is inconsistent: one meta-analysis suggests benefit from treatment in a centre with ICP-driven management, but two meta-analyses suggest no overall benefit from treatment in a centre with ICP-driven management, and maintenance of cerebral perfusion pressure (CPP). The recently updated Brain Trauma Foundation guidelines for management of severe TBI recommend an ICP threshold of 22 mm Hg for initiating intensive treatment, an increase of 2 mm Hg compared with previous editions. However, the practical relevance of such a small change—and the precision of ICP measurement, analysis, and clinical care targets that it implies—have been called into question. Rather, changes in ICP over time are considered to have greater clinical relevance than a single absolute number.

Although population-based targets for ICP and CPP management provide a useful initial basis for care, required target values or ranges differ between patients depending on the specific pathology and should preferably be directed to the needs of individual patients. TBI is pathophysiologically heterogeneous, and the dominant pathological processes can vary between patients, within individual patients over time, and even between different parts of the brain at any given time. Furthermore, preinjury factors, coagulation status, and systemic responses vary between patients. Using a one-size-fits-all management strategy is therefore unlikely to be optimum, and more rational decisions about therapy choice and intensity must account for individual and temporal variations in pathophysiology.

**Surgical management of TBI**

Different types of traumatic intracranial bleeding (haematomas) exist (figure 6), all of which can compress measures of a complex disease in a very complex organ. Therefore, proving efficacy of treatments on the basis of such unidimensional targets is challenging. Furthermore, there is a lack of certainty about the thresholds that justify therapies for raised ICP, all of which have intrinsic hazards; these hazards should be balanced against the harm caused by intracranial hypertension. Therefore, characterisation of a clinically relevant dose (level and duration) of intracranial hypertension remains an important goal and is only just beginning to be quantified in a systematic way. The Lancet Neurology Commission

The difference between mean arterial blood pressure and intracranial pressure (ICP), low CPP can cause ischaemia and excessively high CPP can lead to raised ICP by causing vascular congestion or oedema
The Lancet Neurology Commission

the brain and could be life-threatening. Timely surgery can be life-saving, but this depends on rapid patient transfer to a centre with surgical facilities (section 4). Initial surgical treatment of TBI can be either causally directed (eg, to remove space-occupying intracranial haematomas) or symptomatic (eg, to decrease pressure on the brain to prevent or minimise damage to important structures and prevent life-threatening herniation events). Symptomatic approaches include insertion of an external ventricular drain for drainage of cerebrospinal fluid and decompressive craniectomy, which can be performed in the same setting as the evacuation of a haematoma, or later to treat diffuse brain swelling that is refractory to conservative medical management.

Substantial variation exists in surgical practice, owing to an inadequate evidence base for international guidelines on surgical indications. Additionally, at the level of individual patients, there is debate among clinicians regarding which patients might benefit from some procedures (such as surgical treatment for traumatic intracranial lesions and for raised ICP) and uncertainty regarding the optimum timing of surgery. Surgery might be life-saving and preserve neurological function in some patients, but others might survive with an unfavourable functional outcome, ranging from severe neurological and cognitive deficits to a vegetative state (section 7). Conversely, surgery might not always be necessary. Indeed, a substantial proportion of patients who are managed conservatively have favourable outcomes. Therefore, when deciding whether to operate, medical therapies that might be effective in achieving the same physiological goals as surgery should also be considered. Surgical indications that are too liberal could lead to increased survival with complications of unnecessary surgery in patients with less severe injury, or severe disabilities in those with devastating TBI. Conversely, inappropriate conservative management might result in unnecessary death and disability. The decision to operate is based not only on medical but also on ethical considerations.

Patients' and relatives' views of a meaningful quality of life might be different from our medical perception of a favourable outcome. These differences could depend on several factors, including cultural and religious considerations. If discussion of the expected outcome with relatives is possible, past views expressed by patients on an acceptable quality of life should be taken into account.

Accumulating evidence provides useful support for such decision making. An illustrative example is the use of decompressive craniectomy for intracranial hypertension. Although the procedure can be life-saving by lowering ICP, it is associated with surgical complications, and structural distortions associated with removal of a portion of the skull might cause additional brain injury in some patients. Initially used over a century ago, the intervention came back into use over the past two decades, but given the need to balance risks and benefits, a clear definition of its role was difficult. Two important RCTs have provided useful guidance in this context. The DECRA (Decompressive Cranectomy) trial showed that very early use of decompressive craniectomy for modest rises in ICP in patients with diffuse injuries was associated with worse outcomes. More recently, the RESCUEicp (Randomised Evaluation of Surgery with Craniectomy for Uncontrollable Elevation of Intracranial Pressure) trial showed that, when used for refractory severe intracranial hypertension, decompressive craniectomy could save lives, but resulted in a 9% increase in survival with severe dependence at 6 months. However, by 12 months there were 13% more survivors who were at least independent at home. As the intervention is not uniformly beneficial, individual wishes of patients and their families should be taken into consideration.

Other studies have addressed similar surgical dilemmas. A recent study suggested that in patients with a traumatic acute subdural haematoma, early evacuation was associated with better outcome than a more conservative approach. Similar trends were noted in the STITCH (Surgical Trial In Traumatic IntraCerebral Haemorrhage) study, which reported better outcomes with early surgical management in patients with traumatic intracerebral haematoma. However, the results of the STITCH trial were not statistically significant owing to an inadequate sample size caused by premature discontinuation of the trial by the funding agency. Although surgical trials are challenging, funding bodies should recognise that these and ongoing studies—eg, the RESCUE-ASDH (Randomised Evaluation of Surgery with Craniectomy for patients Undergoing Evacuation of Acute SubDural Haematoma) trial, ISRCTN registry identifier ISRCTN87370545—are crucial for creating a rational evidence base for surgical practice. Clinical decision making could be greatly improved by the identification of patient subgroups most likely to benefit from the intervention, and, importantly, patients who are not likely to benefit.

Rehabilitation after TBI

The sequelae of TBI include long-term physical, cognitive, behavioural, and emotional impairments (panels 1, 6), and difficulties with activities of daily living, community reintegration, work, social life, family functioning, and partner relationships (section 7). Rehabilitation for patients with TBI is a complex process, and varies with time after injury, the nature of TBI, premorbid functioning, and levels of social support. Successful rehabilitation after TBI is determined by patient potential, and depends on both the timely delivery of therapy and the availability of good metrics to characterise the intensity and effects of such therapy. Recent summaries of the available data indicate that strong evidence in support of many rehabilitation therapies is inconsistent or lacking. This is probably because most reviews have focused on evidence from RCTs, which are difficult to design and conduct in this
area, thus limiting the conclusions that can be drawn.32,33,34 Medical or health-care insurance payors often justify bypassing specialised rehabilitation programmes by highlighting the absence of RCT evidence for rehabilitation strategies in TBI, and disparities exist in the level of postacute care provided depending on insurance status and race.25,35,36 Acquisition of stronger evidence in support of rehabilitation therapies is challenging. First, treatment would need to be withheld from the most severely injured patients who are most in need of care, which is uncommon in other specialty areas. Second, rehabilitation schemes should be targeted to the specific needs of individuals, which would complicate the design and implementation of clinical trials.

Different rehabilitation interventions are appropriate at different phases after injury (panel 9). In the subacute phase, the focus is typically on retraining activities of daily living and adjusting environmental factors that enable discharge home. In the longer term, rehabilitation goals focus on community reintegration, such as social participation, return to work, and other meaningful activities that restore quality of life. However, the optimum timing for rehabilitation is debated: some centres advocate early in-hospital initiation,260 but most rehabilitation centres accept patients only when they are trainable—ie, after return of consciousness and once they are out of post-traumatic amnesia. Therefore, in practice, these goals are often addressed, if at all, by different health-care providers, and such services tend to develop in isolation. Rigorous studies are needed on best practice in the acute setting and optimum timing of specific rehabilitation approaches.

The diversity and complexity of the consequences of TBI are best addressed with a comprehensive, holistic approach to rehabilitation delivered by a specialised multidisciplinary team, in close liaison with the patient and family or caregivers (the patient-centred care approach).261 Evidence from two RCTs supports the effectiveness of holistic neuropsychological rehabilitation in both civilian and military populations.342,343 This is consistent with the International Classification of Functioning, Disability and Health (ICF), which provides a framework for understanding disability that is endorsed by WHO.25 An important feature of the ICF is that it goes beyond traditional biomedical approaches to assessment of disability, providing a biopsychosocial, integrative, and comprehensive approach that incorporates factors such as health condition, body structure and function, activities and participation, and various contextual factors (personal factors and environmental factors) relevant to the patient. This is crucial, because the level of functioning for a patient is determined not only by what is happening at the level of the body, but also by how the environment can affect overall disability level. This approach facilitates identification of rehabilitation needs and targets for intervention (panel 10). Further research on rehabilitation needs, type, quality, and effects of services is needed to guide clinicians in the use of appropriate interventions and policy makers in the development of rehabilitation services for individuals with TBI.

**Future goals for intervention studies and guideline development**

Clinical care for patients with TBI is often broadly based on international or local clinical guidelines. However, weaknesses in available evidence confound strong guideline recommendations, and most guidelines fail to capture the complexity and heterogeneity of TBI and its sequelae. The shortcomings in guidelines reflect the limitations of clinical trials in this field. In an attempt to increase the likelihood of demonstrating treatment effects, many clinical trials of medical and surgical interventions for TBI have involved strict protocols and recruitment criteria, typically restricted by age, GCS score, and comorbidities. Despite these restrictions, such trials have largely failed to show benefit, perhaps in part because they have not accounted for disease heterogeneity and hence treatments have not been matched to individual patients or groups of patients.25,35,36–38 In studies that have recorded a clinical effect of an intervention,38 selected patient groups and small sample sizes have often limited the generalisability of the results to the wider population of patients with TBI.

In view of the substantial knowledge gaps about optimum management and the challenges of conducting clinical trials of interventions for TBI, alternative approaches to evidence generation are needed for the development of robust guidelines for best practice. For example, conventional evidence-generation methods such as RCTs could be supplemented with CER (section 9), in combination with high-quality observational studies, to determine optimum medical, surgical, and rehabilitation interventions and care models.

---

**Panel 9: Categories of rehabilitation interventions for traumatic brain injury**

**Restitutional rehabilitation**

- Strategies that focus on strengthening or re-establishing previously learned patterns of behaviour through repetition and rehearsal
- Example: repeated exercises and drills aimed at restoring specific cognitive domains, such as attention307

**Compensatory rehabilitation**

- Strategies that exploit intact strengths to substitute for impaired functions
- Example: use of assistive technology (eg, calendars, paging systems, electronic memory devices, and alarms) for mild-to-moderate memory impairment38 and errorless learning strategies for severe impairment320

**Adaptive rehabilitation**

- Strategies that accommodate residual impairment or disability through reappraisal of self-perception (eg, cognitive restructuring); this relates to psychosocial adjustment after injury
- Example: problem-focused coping and management of self-efficacy beliefs (eg, reduced use of avoidance, wishful thinking, and emotional restrictions) to promote positive psychosocial adjustment308

For more on the International Classification of Functioning, Disability and Health see http://www.who.int/classifications/icf/en/
Future approaches to management and guidelines for best practice need to account for the clinical and mechanistic heterogeneity of TBI and enable therapies to be more carefully matched to patients. Clinical studies should be designed to identify (sub)groups of patients of sufficient size in whom the target mechanism is dominant. Patient stratification for clinical and research interventions will depend on improved characterisation of initial severity and injury mechanisms (section 6). Advances in outcome assessment are needed for rigorous evaluation of therapeutic effects (section 7), while improvements in prognostic schemes could inform research design, facilitate comparisons between studies, and provide opportunities for comparative audits to improve quality of health-care delivery (section 8).

Besides these general considerations, progress in specific aspects of care could lead to improved management. For example, technical advances in invasive and non-invasive monitoring of blood flow, brain metabolism, and electrical activity combined with neuroinformatic methods could provide novel approaches to targeted therapy development and implementation in the ICU setting (section 6). Studies of surgical interventions for TBI should focus on identification of subgroups of patients most likely to benefit from surgery, rather than investigate its use across all possible patients. Future guidelines should allow a flexible approach to take into consideration non-medical factors such as patient and family preferences and beliefs about the value of life and acceptable levels of disability. There is a clear need for studies to inform guidelines on rehabilitation approaches and optimum timing of rehabilitation in TBI. Such guidelines would need to take into account the growing evidence that the diversity of disability after TBI is best addressed through a holistic approach to rehabilitation delivered by a multidisciplinary team.

A change in focus in the clinical management of TBI is required, with interventions based on an understanding of the pathophysiology and clinical needs of individual patients. Implementation of such an individualised approach to management should occur in the context of robust evidence-based guidelines. Thus, new studies need to be rapidly integrated into the evidence base and translated into guidelines that reflect the latest findings—aspirations that are being addressed through the development of living systematic reviews and living guidelines (section 9). Implementation of such guidelines will necessitate effective transfer of the latest knowledge into clinical practice.

Key messages and recommendations

Key messages

(1) Evidence underpinning guidelines for medical, surgical, and rehabilitation interventions for TBI is weak.

(2) Existing guidelines for clinical management, based on population targets, promote a one-size-fits-all approach and do not take into account clinical and mechanistic variability, either between patients or within patients at different stages of injury evolution.

(3) Existing guidelines are not implemented consistently between centres and across geographical regions.

Recommendations

(1) Robust evidence is needed to inform guidelines on medical, surgical, and rehabilitation interventions, and hence improve outcomes for patients with TBI. Consensus-based guidelines might be needed for aspects of management for which evidence is not clinically definitive.

(2) Clinical studies that account for the clinical and mechanistic variability of TBI are needed. New evidence-based guidelines should emphasise implementation of best practice in the context of an understanding of individual pathophysiology and clinical needs, and permit flexibility to achieve an individualised approach to management.

(3) Information campaigns to improve awareness among clinicians about guidelines and recommendations for best practice are needed.

Section 6: Characterisation of TBI—the path to precision medicine

Detailed characterisation of initial injury severity and type is needed to stratify patients with TBI for optimum clinical management. Conventionally, the initial severity of TBI has been classified as mild, moderate, or severe on the basis of assessment of the level of consciousness, measured with the GCS (figure 2). However, this unidimensional classification ignores the mechanistic heterogeneity of TBI. Pathoanatomical insights into the nature of TBI have come from neuropathology studies,
which have highlighted the importance of ischaemic\textsuperscript{350} and inflammatory\textsuperscript{351} responses after TBI, and have led to the recognition of diffuse axonal injury\textsuperscript{352,353} and CTE\textsuperscript{354} as specific entities in the acute and chronic phases of TBI, respectively.

In TBI, as in other diseases, specific interventions and management strategies need to be tailored to the characteristics and needs of individual patients, moving away from the conventional one-size-fits-all approach (section 5).\textsuperscript{355} Improved characterisation and better understanding of pathophysiology in individual patients will be necessary to permit appropriate targeting of therapy and evaluation of outcome. This approach reflects the concept of precision medicine, as advocated by the US National Academy of Science,\textsuperscript{356} which is defined as “an approach to disease treatment and prevention that seeks to maximize effectiveness by taking into account individual variability in genes, environment, and lifestyle”.\textsuperscript{357} Detailed characterisation of injury severity and type can also be used in research to classify groups of patients with similar disease mechanisms to develop and test novel therapies in RCTs or for comparative audits to identify best practices (section 9).

Opportunities for improvements in the characterisation of TBI come from progress in the fields of genomics, blood biomarkers, and advanced magnetic resonance imaging (MRI), as well as new approaches to pathophysiological monitoring, coupled with informatics to integrate data from multiple sources (figure 7). These technologies are at varying stages of maturity in terms of integration into TBI clinical care: some, such as genomic stratification for therapy and outcome prognostication, are at a very early stage of development, while others, such as use of the blood biomarker S100 astroglial calcium-binding protein B (S100B) to stratify patients for CT imaging during the acute phase, have already been integrated into some clinical guidelines,\textsuperscript{358} although not widely accepted.

In this section, we consider current approaches to characterisation of TBI, discuss the continuing relevance of neuropathological studies, and explore how incorporation of emerging technologies could improve disease characterisation and monitoring to advance the aims of precision medicine in TBI. We also consider the challenges and opportunities in integrating multiple sources of data to facilitate translation of these aims. In subsequent sections, we discuss the need for multidimensional approaches to outcome assessment in patients with TBI (section 7), and consider how linking initial severity and pathoanatomical characteristics of TBI to multiple outcome domains could lead to improved prognostic models (section 8), with substantial benefits for patients and their families.

Current approaches to classification and characterisation of TBI

There are wide variations in TBI type and severity. Additionally, the full, integrated picture of TBI comprises a range of pathological changes—eg, diffuse axonal injury, contusions, brain swelling, and brain(stem) compression by extracerebral haematomas—which contribute in varying degrees to the different clinical pictures in individual patients. It is common to separate penetrating TBI from closed TBI because the injury biomechanics are very different and the infection risk in penetrating TBI is higher. The management principles therefore differ substantially between penetrating and closed TBI. However, there has been little attempt to use the full range of pathoanatomical lesions—within both closed and penetrating TBI—in a systematic way as a basis for rational planning of management.

Classification of TBI severity is also challenging: presentation can range from a hit to the head with symptoms of disorientation or some alteration of consciousness that quickly resolves, to high-energy insults leading to loss of consciousness and coma. There are currently no refined criteria for classification of TBI severity. The GCS\textsuperscript{359} is the most commonly used approach to quantify the clinical severity of TBI\textsuperscript{360} (figure 2), but this is relatively crude and does not reflect different pathoanatomical subsets of TBI. Moreover, the increasing use of prehospital sedation and tracheal intubation often confounds assessment with the GCS and has reduced its usefulness as a metric of injury severity.\textsuperscript{361}

Existing International Classification of Diseases codes\textsuperscript{362} also do not adequately capture severity of TBI.\textsuperscript{363}
Alternative TBI coding taxonomies—including the Abbreviated Injury Scale (AIS), which categorises severity of intracranial and extracranial injury,358 and the Marshall classification system, which is based on head CT findings359—are anatomically oriented and summarise the type, location, and severity of injuries. The AIS, which is used globally by trauma registries, classifies each patient’s regional anatomical injuries, from which an aggregated Injury Severity Score can be derived.358 However, scoring with this scale is generally retrospective, and severity ratings can be influenced by factors such as admission to hospital or ICU or by decisions regarding surgical intervention. The Marshall classification system is unidimensional, being restricted to CT findings, and is essentially based on only two discriminating features: the need for surgery and radiological signs of raised ICP.

There is increasing recognition that appropriate characterisation of the initial type and severity of TBI should not be restricted to one dimension (eg, GCS or CT classification), but should include multiple domains such as clinical and pathophysiological features, neuroimaging findings, and other factors that might influence clinical outcome.

**Brain banks and lessons from neuropathology**

Efforts to improve clinical characterisation of TBI can be informed by neuropathological research, which has provided a foundation for our current understanding of key pathological processes in TBI, including diffuse axonal injury,152,153 ischaemia,160 neuroinflammation,151 and amyloid deposition in association with neurodegeneration.21,151,360 However, despite the insights afforded by detailed neuropathological examination of human brain tissue,164 there are remarkably few research archives containing biospecimens suited to studies in TBI. Indeed, only one comprehensive archive of human brain tissue exists—the Glasgow TBI Archive166—which is dedicated to systematic review373 concluded that this effect might be limited to patients with severe TBI. These contrasting findings might reflect an effect of an interaction between age and genotype on outcome.370 They found that, although there was no effect of APOE genotype for all age groups combined, children (<15 years) and young adults (<30 years) who were ε4 carriers had a deleterious effect on TBI outcome360 could not be replicated in a larger cohort by Teasdale and colleagues,382 and a recent systematic review371 concluded that this effect might be limited to patients with severe TBI. These contrasting findings might reflect an effect of an interaction between age and genotype on outcome.370 APOE genotype has also been variably shown to modulate TBI outcome.360 One large study360 of patients with TBI undergoing rehabilitation showed that ε4 carriers had worse outcomes 2 years after injury compared with ε2 or ε3 carriers. However, initial findings that the ε4 allele had a deleterious effect on TBI outcome360 could not be replicated in a larger cohort by Teasdale and colleagues,382 and a recent systematic review371 concluded that this effect might be limited to patients with severe TBI. These contrasting findings might reflect an effect of an interaction between age and genotype on outcome.370 They found that, although there was no effect of APOE genotype for all age groups combined, children (<15 years) and young adults (<30 years) who were ε4 carriers experienced significantly worse outcomes than ε2 or ε3 carriers, suggesting that younger age does not protect against the adverse effects of ε4 carriage on outcome after TBI. Despite extensive research, the precise relation between APOE genotype and TBI outcome after TBI is highly variable (sections 7, 8), and some of the differences in disease course are likely to be accounted for, at least in part, by genetic variability between patients (figure 8). In oncology, precision-medicine approaches are based mainly on knowledge of the molecular genetics of the tumour, whereas in TBI, a key focus for precision-medicine strategies is the genomics of the host response, which can modulate injury course as well as repair. Compared with oncology, the genomic characterisation of TBI is in its infancy. If further developed, identification of relevant genetic risk or protective factors early after TBI could potentially be used to inform individualised management approaches and thus improve outcomes.

The most extensively studied gene in the field of TBI is apolipoprotein E (APOE), which encodes a protein that has a central role in lipid transport in the central nervous system, including movement of cholesterol into cells to aid repair of damaged neurons.37 Three APOE variants (alleles) have been characterised—ε2, ε3, and ε4—of which ε4 has been reported to have proinflammatory effects in mice and to increase the risk of late-onset Alzheimer’s disease in humans.380,381 In TBI, although the risk of late neurodegenerative disease scales with injury severity, presence of an ε4 allele might modulate this risk.368 Possession of an ε4 allele has been found to double the risk of dementia in the general population, but this risk might be increased by up to 10 times in people with TBI.383 Moreover, in a group of patients who had sustained a single mild TBI, only those with an ε4 allele had an increased risk of dementia in the long term compared with the general population.379
outcome remains uncertain. Other genetic targets of interest include the mitochondrial DNA haplotype, mediators of inflammatory responses, and genetic factors involved in regenerative and neurotrophic responses, such as brain-derived neurotrophic factor (BDNF).

The applications of emerging genomic information to TBI care and research are evolving (figure 8). Potential roles include better characterisation of injury, identification of patients at increased risk of progressive damage, and therapeutic stratification to facilitate an individualised approach to management, as well as more accurate prognostication (section 8), and identification of molecular targets for future drug development. Current evidence is limited by insufficiently powered studies. Exploration of the role of genetic characterisation for precision medicine in TBI requires large, prospective studies that can be used to simultaneously analyse the effects of multiple genes in well defined populations. APOE is an obvious candidate, but genes with a greater predictive value for early catastrophic clinical outcomes, such as death, haemorrhagic events, or acute brain swelling, might be of greater clinical use.

### Blood biomarkers

There is an unmet medical need for rapid blood-based biomarker tests, as an adjunct to imaging studies, to optimise diagnosis, track disease progression, and improve outcome prediction (section 8) in TBI to facilitate individualised management. Substantial scientific advances in the past decade have resulted in identification of a large number of blood-based protein biomarkers that are relevant to different phases of TBI (figure 9; appendix p 8). Ongoing research efforts are yielding new classes of biomarkers, including metabolomic and lipid markers, microRNAs, and exosomes. All of these hold potential for diagnosis, prognosis, and therapeutic stratification, but are not yet in advanced clinical development.

Acute-phase biomarkers—eg, S100B, glial fibrillary acidic protein (GFAP), and ubiquitin C-terminal hydrolase-L1 (UCH-L1)—have substantial potential for use in the prehospital setting and emergency departments where large numbers of patients present with head trauma, the vast majority of whom will have normal brain CT findings. Compared with other stages of TBI management, protein biomarkers for the acute phase are probably closest to clinical implementation, and one of these—S100B—is already included in an algorithm in Scandinavian guidelines to triage patients with mild TBI for CT imaging after head trauma. Despite the multitude of candidate molecules proposed, translation and widespread adoption into clinical diagnostics remain elusive. Progress has been hampered by studies with small numbers of patients, variability in sample processing and storage, differences in assay techniques used, lack of reference standards, and incomplete understanding of underlying biomarker biology. Transport of biomarkers from damaged tissue to the blood is much more complex in the brain than in the heart owing to additional clearance pathways, such as the cerebrospinal fluid and glymphatic systems. It is therefore less straightforward to relate brain-specific biomarker concentrations to the presence and extent of brain damage in TBI than it is to relate cardiac troponin concentrations, for example, to the extent of heart damage following myocardial infarction. Moreover, small lesions in vital brain areas can lead to deep coma, even though numbers of cells lost, and thus changes in biomarker concentrations, might be relatively small, whereas more extensive damage

**Figure 8: Potential effects of genetic variation on clinical course and outcome of traumatic brain injury**

Genetic factors might influence an individual’s risk of and response to traumatic brain injury (TBI), contributing to functional outcomes in the short and longer term. Although still speculative, possible applications of such knowledge could include use of genetic factors that might modulate TBI outcome (eg, apolipoprotein E [APOE] genotype) in a comprehensive prognostic scheme, or stratification of patients for clinical trials of treatments on the basis of genotypes that modulate the host response (eg, proinflammatory response), influence regenerative capacity (eg, brain-derived neurotrophic factor [BDNF] concentrations), or affect mitochondrial biology.

**Mitochondrial DNA haplotype**

A cluster of genes in the mitochondrial DNA, inherited as a single unit from the mother, a mitochondrial DNA haplogroup is a group of similar haplotypes that can be traced back to a single common ancestor along the matrilineal line.

**Glymphatic system**

A functional pathway for cerebrospinal fluid and interstitial fluid exchange in the brain, allowing waste clearance from the central nervous system.

**MicroRNAs**

A novel class of small, noncoding endogenous RNAs that regulate gene expression in a sequence-specific manner.

**Exosomes**

Small membrane-based vesicles with various compositions that are released into and can be detected in extracellular biofluids (eg, blood), exosomes have a range of biological functions and are involved in several pathological processes.
Standard clinical MRI provides greater sensitivity than CT for parenchymal lesions, especially in the posterior fossa, brainstem, and superficial cortical areas (figure 10). Advanced MRI can be used to characterise pathophysiology from ictus to outcome, and could have prognostic value across the range of outcomes, from recovery after a postconcussive state in mild TBI to emergence from coma in the most severely injured patients. Diffusion tensor imaging and susceptibility-weighted imaging are particularly sensitive for mapping diffuse axonal injury and the microhaemorrhages that accompany it (figure 10), and functional MRI can be used to map functional disconnections that underlie clinical deficits. Although MRI protocols are speeding up, when compared with CT, MRI scanning generally takes longer (30–45 min), limiting its use in emergency settings.

Although the potential importance of advanced MRI methods for refining characterisation of TBI is undeniable, generalisability to everyday clinical practice remains an enormous challenge. Readily available and inexpensive MRI-compatible clinical monitoring equipment is needed to allow use in the most injured patients. More open (often low-field) MRI systems might ease some logistical difficulties in this context. However, use of low-field systems would be contrary to prevailing trends: 3T systems are increasingly the standard field strength for clinical use, and 7T systems are on the cusp of approval for clinical imaging.

Regardless of the field strength of MRI, regulatory authorities and vendors must address cross-centre (and inter-device) comparability of images, particularly with regard to quantitative assessments. Complete standardisation might not be possible. CT images can be calibrated in Hounsfield units, but such a calibration system does not exist for MRI. Experience of international collaborations in TBI research, however, does suggest that harmonisation of protocols can and should be achieved. Such harmonisation is essential for large, multicentre clinical studies. Translation of research protocols to routine clinical imaging will be a challenging task that requires extensive interaction between vendors, MRI experts, and regulatory authorities.

**Physiological monitoring**

Current neuromonitoring technology offers opportunities to dissect pathophysiological mechanisms to define individualised treatment targets and personalise ICU management of TBI. Such technological approaches include the use of advanced signal processing of ICP waveforms to derive measures of autoregulation, and the addition of more novel sensors to monitor oxygenation, metabolism, and the inflammatory response, as well as cortical electrical activity and spreading depolarisations.

The combination of these different sources of information provides a more complete understanding of brain physiology than is possible with measurement of a single variable, and preliminary evidence from a recent study shows promise for clinical implementation.
incorporate all the monitoring modalities into a single tool, and guidelines for monitoring of the partial pressure of brain tissue oxygen (PbtO2) and for microdialysis are in their infancy. The idea of identifying clinically important and treatable parameters, not immediately obvious from raw bedside data, using computational and informatics techniques, is compelling and potentially rewarding, but challenging. In recent years, the field of machine learning has developed new and sophisticated statistical and computational techniques to process high-dimensional data, which have diverse applications in science and engineering. Such approaches (so-called big data solutions) might also prove valuable for the analysis of time-dependent neuromonitoring data, both for real-time prediction of events and for characterisation of physiological states that respond to specific therapies, thus facilitating clinical decisions about critically ill patients.

Improved characterisation and classification of TBI will, ultimately, require integration of information not only from multimodal monitoring methods, but also from a range of sources including clinical, neuroimaging, genetic, and biomarker techniques (figure 7). Such integration of information will be a considerable endeavour, but has the potential to enable classification of patients into groups with more homogeneous pathophysiological mechanisms for targeted trials of novel neuroprotective interventions. This approach depends on access to large data sources and substantial input from the field of neuroinformatics and computational sciences, both of which require interdisciplinary and intercentre collaboration (section 9).

Figure 10: Detection of structural brain damage after traumatic brain injury with computed tomography and magnetic resonance imaging
(A) Computed tomography (CT) scan from an adult patient with traumatic brain injury (TBI) on admission to hospital (left panel), and magnetic resonance imaging (MRI) scans (fluid-attenuated inversion-recovery sequence [FLAIR, middle panel] and gradient-echo sequence [GRE, right panel]) within 2 days of admission. MRI shows an anterior brainstem haemorrhage and surrounding oedema (green arrows) that was not detected with CT, and haemorrhagic lesions in the posterior brainstem, in the region of the fourth ventricle, and in the posterior temporal lobe (white arrows), which are most conspicuous on the GRE sequence (sensitised to blood products). (B) MRI scans with a FLAIR sequence (left panel) and susceptibility-weighted imaging (SWI; right panel) from an adult patient with TBI obtained 1 day after injury. The large abnormality on the left arises from an intracranial monitor probe (green arrows) and is seen on both the FLAIR and SWI scans. However, many of the microhaemorrhages associated with diffuse axonal injury (white arrows) are visible only on the SWI sequence, highlighting the greater sensitivity of SWI compared with FLAIR sequences for detection of microbleeds after TBI.

Key messages and recommendations

Key messages
(1) Methods of diagnosis and classification of patients with TBI are insufficient to permit targeting of current and new therapies to the needs of individual patients.
(2) Few tissue archives containing specimens suited to TBI research exist, and their future sustainability is insufficiently guaranteed.
(3) Advances in genetics, biomarker research, advanced neuroimaging, and pathophysiological monitoring promise improved characterisation of clinical and mechanistic types of TBI, as well as outcome and prognosis, but progress is limited owing to small study sizes.
(4) Progress in biomarker and neuroimaging studies is hampered by lack of standardisation.
Developments in digital analysis of large datasets have the power to improve clinical decision making, especially for critically ill patients with TBI, in which the volume of physiological monitoring data is challenging.

**Recommendations**

1. Research is needed to improve the precision of diagnosis, classification, and characterisation of TBI using multidomain approaches.
2. Investment is needed to secure existing research archives and develop new archives of well characterised human tissue to support collaborative research in TBI.
3. Support is needed for studies that use emerging technologies to allow improved targeting of treatment strategies to individual patients on the basis of clinical and pathophysiological characteristics.
4. Regulatory agencies should mandate standardisation (or at least harmonisation) of biomarker technology and advanced neuroimaging to facilitate data sharing in large studies and accelerate improved management and outcomes for patients with TBI.
5. Collaboration with the field of neuroinformatics and computational sciences, coupled with big data solutions, are needed to develop decision-support systems, especially for critically ill patients with TBI.

**Section 7: Assessment of TBI outcome—towards multidimensional approaches**

While improved characterisation of initial injury severity and type is a prerequisite for the development of precision-medicine approaches to TBI (section 6), more refined assessment of clinical outcome is equally essential to measure the effectiveness of early treatments and guide individualised management in the postacute phase. Accurate characterisation of outcome is also necessary to evaluate patterns of recovery and deterioration in the long term, to predict long-term care needs for patients and their families, to understand the impact of clinical care, to compare outcomes between centres, and to assess the efficacy of conventional and novel therapeutic interventions.

Functional outcome is as relevant, or perhaps more so, than mortality in TBI owing to the high rate of disability in survivors, and is generally assessed with the Glasgow Outcome Scale (GOS)\(^{427}\) or its extended version (GOSE; figure 12).\(^{428}\) Despite their clinical appeal, the GOS and GOSE are based on broad categories and therefore insufficiently account for the multidimensional nature of outcomes after TBI, which can include long-term changes in functional, physical, emotional, cognitive, and social domains.\(^{29,112}\)

In this section, we discuss the limitations of current approaches to outcome assessment and classification in TBI, and we emphasise the need for multidimensional outcome scales for clinical practice and research, underlining challenges in the development of such approaches.

**Current approaches to outcome assessment**

At present, characterisation of outcome in patients admitted to hospital with TBI is based mainly on the GOS\(^{427}\) or the GOSE, particularly for research purposes.\(^{509,429}\) These are valuable but relatively simplistic scales for assessment of global outcome. The GOS was introduced by Jennett and Bond in 1975\(^ {427}\) as a five-category scale to capture functional outcome: alterations in major roles such as work and independent living, as assessed by the investigator, are used to summarise the effects of diverse changes caused by injury. Although attractively simple, the limited sensitivity of the GOS led to the development of the GOSE, in which the categories of severe disability, moderate disability, and good recovery are subdivided into lower and upper subcategories (figure 12).\(^ {428}\) A structured assessment was proposed to facilitate standardised administration.\(^ {429}\) However, despite more detailed outcome characterisation, the eight-category GOSE scale still lacks sensitivity to changes within specific domains of function (eg, cognition, emotional well-being, and life satisfaction). Even patients with mild TBI—who would be considered to have good recovery on the GOSE—often have anxiety, depression, post-traumatic stress disorder, and clinically relevant...
Postconcussion symptoms, including, but not confined to, headache, dizziness or vertigo, fatigue, irritability, disordered sleep, and memory and concentration problems.\textsuperscript{443} Postconcussion symptoms pose particular challenges for outcome assessment because their occurrence depends on complex interactions between physiological, psychological, and social factors. Furthermore, they are not entirely specific to TBI as they can occur in patients with orthopaedic injuries or in healthy individuals.\textsuperscript{444,445}

The GOS and GOSE are not universally used for formal categorisation of outcome in everyday clinical practice, as summary outcome measures do not allow clinicians to target management of specific problems in individual patients. They are also unlikely to facilitate future precision-medicine approaches by enabling identification of subgroups of patients in whom mechanistically specific therapies can be used. Furthermore, the GOS and GOSE do not provide sufficient discrimination to reliably detect small, but clinically relevant recovery or deterioration of function and effects of treatment over time.\textsuperscript{446} The considerations suggest the need for detailed assessments that are sensitive to smaller transitions in outcome and that take account of a range of aspects of outcome.\textsuperscript{447,448} Nevertheless, summary or integrated measures of outcome could still provide a useful basis for allocating patients to broad care pathways, and such applications are worth developing.

Insensitivity of outcome metrics also decreases the chances of detecting treatment effects in clinical trials, and this problem is exacerbated by the common practice in TBI of dichotomising the GOS or GOSE into two categories: unfavourable (dead, vegetative, severe disability) versus favourable (moderate disability, good recovery). This approach is statistically inefficient and should be discouraged.\textsuperscript{449,450} Currently recommended approaches for analysing GOS and GOSE data from clinical trials involve the use of a proportional odds analysis (evaluation of a shift across the categories of outcome) or a sliding dichotomy approach (in which the GOS or GOSE is still dichotomised, but the point of dichotomy varies according to individual baseline prognostic risk).\textsuperscript{451} However, as above, even this more refined application of the GOS and GOSE would still be unsatisfactory for assessment of patients with mild TBI, who might achieve the best possible outcome (GOSE score 8) but still have long-term health problems across a number of domains.\textsuperscript{452,453}

In addition to the GOS and GOSE, a multitude of instruments for assessing outcome is available: recent overviews have identified nearly 1000 (mostly non-overlapping) outcome assessment instruments for TBI (appendix p 9).\textsuperscript{454–457} Diversity in outcome assessment is an asset in clinical practice, and has been embraced for many years, particularly in the management of TBI after the acute stage. However, this diversity is a major obstacle to research progress in TBI owing to difficulties in selecting single endpoints for use in clinical trials and in pooling of data and conduct of meta-analyses. Moreover, although different assessments might be needed for different purposes, their relevance is debated and there is no consensus on a key set of assessments.

### Multidimensional assessment of outcome

Heterogeneity in the consequences of TBI and the wide variety of short-term and long-term recovery patterns place high demands on outcome assessment. It is increasingly evident that a single outcome parameter is insufficient to demonstrate treatment effects in the clinical setting or to serve as an endpoint in clinical trials, and that multidimensional outcome scales that cover a broad range of domains (figure 13)\textsuperscript{458–460} are essential to describe the consequences of TBI. Crucially, these scales should include outcome domains such as cognitive deficits, psychological health, and quality of life (including the effects of common symptoms such as sleep disturbance and pain).\textsuperscript{457–459}

Development of multidimensional outcome assessments is a challenging aspiration and various approaches need to be considered: (1) identification and standardisation of a core set of outcome instruments; (2) recognition that patients who have different grades of outcome will need different assessment tools, both generally and to address specific problems that are more relevant to a specific outcome category or severity of impairment; and (3) development of more refined global assessments or composite endpoints.

Importantly, acceptance of the need for multidimensional outcome measures by regulatory authorities is essential. Although it is commonly perceived that regulators require the use of the GOS or GOSE as an efficacy parameter for clinical trials, experience suggests that they are open to

considering other early or late outcome measures if there is evidence to support their use and clinical validity. In the USA, the Food and Drug Administration (FDA) has recently implemented a formal qualification process for clinical outcome assessments that should facilitate adoption of a range of instruments in TBI clinical trials. Collaboration between the FDA and clinical investigators has been established in the context of the TBI Endpoints Development project.

Identification of a subset of assessments that cover key dimensions of outcome beyond those assessed with the GOSE, and that could be used across studies and over time, would be a major step forward. Assessment methods have different strengths and weaknesses, and few can be applied across the complete TBI severity spectrum. Approaches considered include health-related quality-of-life measures, neuropsychological assessments, and composite endpoints. Health-related quality-of-life assessment can effectively combine different domains, but a quality-of-life measure in isolation would still only rarely be considered adequate as an endpoint in TBI clinical trials, and people with severe injuries might be too cognitively impaired to complete these assessments. The reliability of exclusively self-reported measures can be hampered by limited self-awareness of deficits, necessitating access to caregivers’ views, which might be different and possibly more accurate than those of patients. Neuropsychological tests cover a range of domains, and provide a sensitive index of impairments, but can be challenging to complete for TBI survivors: in a trial of hypothermia, only just over half of patients with severe TBI completed a cognitive assessment at 6 months. Moreover, interactions might exist between cognitive performance and the presence of psychological disorders such as post-traumatic stress disorder or depressive symptoms, which might affect the reliability of neuropsychological assessment results.

The use of different approaches and combinations of instruments would depend on the level of disability—eg, patients who have persistent postconcussion symptoms after mild TBI would have assessment needs different from those with disorders of consciousness after severe TBI. This need to accommodate different outcomes or levels of severity of impairment is concordant with the concept of the sliding dichotomy for outcome analysis of GOS or GOSE scores, in which the point of dichotomy of this measure is differentiated by initial baseline risk. Different outcome instruments might map to different levels of disability (figure 13), and accurate characterisation of specific problems (eg, paroxysmal sympathetic hyperactivity, which is common after more severe injuries) can provide a robust base for targeted treatment of these problems.

Composite endpoints have been pioneered in a few clinical trials, including the recent BEST-TRIP trial. However, use of composite scores comprising two or more outcome measures can be problematic with regard to traditional methodological and statistical approaches, whereby a single measure is typically used to calculate the required sample size to reliably detect a treatment effect. In the context of composite scores in clinical trials, selection of a parameter that is likely to change over time might lead to sample sizes with insufficient power to detect effects of other outcomes, whereas use of the measure that is least likely to change could necessitate impractical sample sizes. Other issues with the use of global tests or composite measures include the need to weight individual test components and how best to achieve this, as well as interpretation of the overall results.

There have been major initiatives to develop a core set of standardised multidimensional assessment methods with global measures or composite endpoints that can be used across different diseases. The Cambridge Neuropsychological Test Automated Battery (CANTAB) and the NIH Toolbox are sets of computerised measures designed to assess cognition, emotion, and motor and sensory functions. The Patient Reported Outcomes Measurement Information System (PROMIS) project has developed a set of instruments that can be used across a wide range of chronic conditions. These tools could be useful in both research and clinical settings. Practical problems might, however, hamper implementation of any comprehensive scheme in an international setting (panel II), and completion of all assessments could be challenging for TBI survivors. Further work is therefore needed to establish multidimensional and composite outcome assessments as endpoints for clinical studies of TBI.
Limited availability of many instruments in languages other than English is a major barrier to their use in international settings. Additionally, ensuring cultural applicability of assessment methods is an important challenge when collecting and analysing data across countries. The CANTAB and the NIH Toolbox have the advantage of being language-independent, and the PROMIS instruments are available in many languages; in the context of the Collaborative European NeuroTrauma Effectiveness Research in Traumatic Brain Injury (CENTER-TBI) project (section 9), translations of common outcome assessments have been linguistically validated and will be made available without restrictions to the neurotrauma community. However, such validation is not simple, since it is very time-consuming and resource-intensive, and high priority should be given to the funding of cross-cultural validation of more assessments. Charges and restrictions on proprietary measures are a substantial hurdle in the internationalisation of many instruments. We strongly believe that outcome assessments advocated by the Common Data Elements for TBI should be freely available to the clinical and research communities without charge, and that public funding should support ready access to high-quality instruments. Developing multidimensional outcome tools and novel ways to integrate the various outcome instruments will require collaborative efforts in large-scale studies with novel approaches to data sharing (section 9).

Key messages and recommendations

Key messages
(1) Trauma disturbs the brain in complex ways, affecting multiple outcome domains.
(2) A substantial number of patients with even mild TBI experience long-term pain, sleep disorders, and mental health conditions, including post-traumatic stress disorder and major depression.
(3) Patients with TBI can have late deterioration or recovery of function even 1 year or more after injury.

Recommendations
(1) Multidimensional outcome constructs that quantify the overall burden of disability from TBI need to be developed and validated to guide improved clinical management and support high-quality research.
(2) Understanding of the long-term effects of TBI and implementation of best practice for ongoing care—in particular, for appropriately targeted health management and continuing support in the chronic phase of TBI—should be prioritised by politicians and health-care professionals.
(3) Long-term longitudinal studies using multidimensional outcome measures are needed to better capture the recovery process and occurrence of late deterioration after TBI.
the developments and refinements needed to improve prognostic models and enhance their use.

### Applications for prognostic modelling in TBI

Outcome predictions form an integral part of clinical medicine and serve various purposes—eg, to provide information about expected outcomes to patients and their relatives and to assist with treatment and triage decisions (panel 1). Clinicians’ expectations of patients’ outcomes have an inherent degree of uncertainty, and prognostic models could help to refine these expectations by providing a probability of a specific outcome.

Prognostic models can further be used to inform our understanding of cause and effect, and provide insight into potentially modifiable causes of poor outcomes. However, since an association might not be causal, clinical benefit of correction of a modifiable factor would need to be proven with thorough evaluation of an intervention, preferably in an RCT. Use of prognostic models could also facilitate more efficient design of clinical trials and analysis of trial data, enable adjustment for differences in case-mix when comparing patient series. As outcome depends not only on treatment, but also to a large extent on patient characteristics and injury severity, making comparisons between different patient populations is inappropriate, unless these comparisons are risk-adjusted for differences in case-mix. Prognostic models could be used to provide estimates of expected outcomes for case series adjusted for patient and injury characteristics; any differences between observed and expected outcomes could then be attributed with more certainty to differences in treatment. Adjustment for injury and patient characteristics is particularly relevant to TBI owing to its complex heterogeneity, including differences in injury type and severity between patients.

Similarly, prognostic models could be used for risk adjustment when comparing outcomes between hospitals. Such benchmarking is a specific approach to enable implementation of the best available evidence into practice and to optimise quality of care. It allows continuous comparisons between hospitals and identification of areas for improvement. Ideally, a set of quality indicators for benchmarking would include outcome indicators (eg, mortality rate), process indicators (eg, guideline adherence), and structure indicators (presence of facilities to provide good care). However, the development of quality indicators for TBI is challenging since mortality is a poor outcome metric for benchmarking in TBI: survival with extremely severe disability is generally considered to be an undesirable outcome, and, for many, survival in a vegetative state might be an outcome worse than death. There are currently no broad quality indicators for TBI, and the development of an internationally accepted set of indicators should be considered a high priority to ensure implementation of evidence-based care and to optimise quality of care for patients with TBI.

### Prognostic models for outcome prediction

#### Moderate and severe TBI

Many prognostic models have been developed since the 1970s, with varying methodological quality,462,463 One aim in developing some of these models was to refine efficacy analyses in clinical trials. These models have specifically focused on baseline risk assessment using characteristics available at hospital admission, and on mortality and GOS scores at 6 months after injury as outcomes of interest. For moderate and severe TBI, two sets of prognostic models have been developed on large datasets using state-of-the-art methods: the IMPACT (International Mission for Prognosis and Analysis of Clinical Trials in TBI) models, based on eight large datasets,464 and the CRASH models, based on the database of a large clinical trial.465 However, the development populations for both models were weighted towards severe TBI, and patients with moderate TBI were under-represented;466 thus, an additional focus on moderate TBI is required.

The IMPACT and CRASH models share some key predictors of outcome: age, GCS scores (the full score in CRASH, the motor component in IMPACT), pupillary reactivity, presence of second insults (hypoxia and hypotension), CT characteristics, and laboratory parameters. Most predictive information is contained in the core predictors—age, GCS motor score, and pupillary reactivity—which together explain approximately 35% of the variance in outcome (appendix p 10).464 Both the CRASH and IMPACT models have been extensively validated in cohorts outside the populations of the original studies, an essential step to test the generalisability of a prognostic model beyond the development setting.467 In the absence of external validation, prognostic effects are likely to be overestimated. External validation should therefore be a key requirement for all new models and for the addition of new predictors to existing models.

#### Mild TBI

The sequelae of mild TBI can include physical symptoms, behavioural disturbances, and cognitive dysfunction, any of which could interfere with return to
work or resumption of social activities. Prognostic analyses can enable identification of patients at increased risk of such symptoms, who could then be followed more closely and receive early interventions to alleviate the burden of injury. Mortality is not an appropriate endpoint for prognostic analyses in these patients, and the usefulness of the GOS is doubtful, because although a substantial number of patients with so-called mild TBI might have disabling complaints, most will have outcome scores in the upper segment of the GOS categories. Ceiling effects of the GOS might partly explain why methods for predicting outcome in patients with milder forms of TBI are scarce. More sensitive outcome measures (section 7) as endpoints for prognostic analyses are required, but these have so far been insufficiently or inconsistently investigated. Although prognostic models are now beginning to emerge for mild TBI, they have not been fully validated, their generalisability has not been determined, and they are less well established than those for moderate-to-severe TBI. Therefore, there is an urgent need for robust validation and further improvement of models in this patient group.

**Advancing the science of prognosis in TBI**

The availability of robust and well validated prognostic models for moderate-to-severe TBI is a major step forward. They allow us to deal appropriately with the inherent heterogeneity of TBI populations. However, as these models each explain, at most, only 35% of the variance in outcome, other key patient and injury characteristics are likely to contribute to outcome. Identifying these characteristics could improve prognostication and, if modifiable, could provide therapeutic targets. Genetic variance, advanced neuroimaging, and other precision-medicine features (section 6) might explain part of the residual variance. Inclusion of these features could provide some refinement of prognostic models, but treatment differences and centre effects are also likely to contribute to the variance in TBI outcome.

Various directions for prognostic research in TBI have been identified (panel 13). Prognostic models could be improved by including new predictors, by better characterising existing predictors, by adding new information as it becomes available with disease evolution (dynamic predictors), and by predicting other relevant outcomes. Various studies have explored the prognostic value of new predictive methods, including biomarkers and advanced MRI (section 6), often reporting promising results. However, most have been limited to relatively low numbers of patients and have compared predictions based on admission characteristics (eg, with the IMPACT and CRASH models) with performance of the new predictive method at a later stage (eg, advanced MRI at 1–3 weeks). More rigorous approaches would be to assess the predictive value of new information (eg, MRI findings) obtained at the same time as clinical admission characteristics. Importantly, studies need to have adequate sample sizes, as underpowered studies might produce misleading conclusions, either inflating prognostic effects or missing effects entirely. Prognostic models could also incorporate information that becomes available over time, such as repeated CT imaging, additional MRI scans, or temporal profiles of monitored parameters. Such dynamic predictions are complex and require specific statistical techniques to capture repeated measures from the same patient. Recently developed machine-learning techniques might hold promise for use with complex data structures, but they have performed inconsistently in predicting outcome after TBI.

We need to focus on the incremental value of new or extended predictive markers—ie, their prognostic value beyond readily available characteristics. Such evaluation should be phased, starting with technical validation of marker measurements, followed by evaluation in small patient series, and, ultimately, with rigorous validation in independent cohorts. Repeated validation over time with updating of models should be done to account for the changing epidemiology of TBI (section 1) and changes in care processes and treatments. Several statistical measures have recently been proposed to quantify the effect of a marker on classification. Decision analyses and cost-effectiveness analyses should also be done to assess the clinical usefulness of any new marker.

A related challenge is to make predictions optimally targeted to the specific clinical setting. The CRASH model was developed with variants for HICs and LMICs. Further site-specific customisation could be attempted using advanced statistical approaches such as random effects models, which take into account the clustering of patients within sites and incorporate this clustering into prognostic estimates. Such model adaptations aim to improve the calibration of predictions for individual patients in specific settings, recognising that trauma organisation and treatment policies might differ between sites or change over time.
International collaborative studies that collect high-quality data on large numbers of patients across the full injury severity spectrum, including mild TBI, are required to advance the science of prognosis in TBI (section 9). The absence of good prognostic models for mild TBI highlights an important gap in our knowledge that requires attention. Outcome measures are required, beyond the currently established GOS and GOSE assessments, that incorporate cognitive, psychosocial, health-related quality-of-life, and other patient-reported outcomes. Prognostic models that include such multidimensional measures and that extend over a long timeframe to predict chronic outcomes need to be developed (section 7).

Key messages and recommendations

Key messages
(1) Prognostic models can help clinicians to provide realistic information to patients and families and can facilitate treatment and triage decisions, but existing models for moderate-to-severe TBI require refinement and there are no well-established models for mild TBI.
(2) TBI affects multiple outcome domains (section 7), but current prognostic models, which focus mainly on mortality and GOS scores, cannot predict this range of outcomes.
(3) A validated set of quality indicators is essential for the benchmarking of quality of care, but none exists for TBI.

Recommendations
(1) There is an urgent need for further development, validation, and implementation of prognostic models in TBI, especially for mild TBI.
(2) Support is needed for the development of new prognostic models that can be used to predict outcomes beyond mortality and GOS scores, and that reflect multiple domains including cognitive, psychosocial, and health-related quality-of-life outcomes.
(3) Efforts are needed to develop a set of quality indicators for TBI that includes structure, process, and outcome metrics.

Section 9: New directions for acquiring and implementing evidence

The heterogeneity of the population at risk of TBI, variations in injury patterns, and wide disparities in systems of care pose particular challenges for the generation and implementation of clinical evidence in the field of TBI. Evidence underpinning guidelines for trauma care pathways and clinical interventions is often weak, and recommendations are inconsistently implemented (sections 4, 5). Conventional approaches to reduce heterogeneity in RCTs of medical or surgical interventions have mostly involved use of strict enrolment criteria and tight protocols, typically focusing on age, GCS scores, and preinjury morbidity, while neglecting differences in injury mechanisms (section 5). This approach has reduced the generalisability of results, while increasing duration and therefore costs of studies. Moreover, most multicentre RCTs in TBI have failed to demonstrate efficacy of interventions in the populations studied.343,348 A recent systematic overview of RCTs in acute moderate-to-severe TBI identified 191 completed RCTs, of which 26 were considered to be robust (high quality, with sufficient numbers). Of these, only six showed a statistically significant effect—three positive and three negative. The authors concluded that considerable investment of resources had resulted in very little translatable evidence.348

There is a growing appreciation that the current emphasis on the pre-eminence of RCTs for clinical evidence generation might be mistaken.485 We must rethink approaches to the generation, analysis, and implementation of evidence.487,488 An alternative approach could be to exploit the heterogeneity of TBI in terms of disease type, management, and outcome using CER, rather than attempting to reduce the heterogeneity, as is common in RCTs. Such research would enable assessment of therapies in real-world conditions. CER requires large studies, international collaboration, and advanced statistical expertise. It also demands a change in research culture to recognise CER outputs as high-quality evidence, and to embrace broad data sharing. Large-scale collaborative studies and data sharing are also needed to generate high-quality research on the characterisation of TBI, outcome assessment, and prognosis (sections 6, 7, 8). Such research would help to advance precision-medicine approaches, to target treatments to individual patients on the basis of clinical and pathophysiological characteristics. Such paradigm changes are endorsed by the InTBIR, a collaboration of funding agencies. Global collaborations modelled on the InTBIR need to be promoted.

In this section, we evaluate the application of CER approaches, and explore the advantages and challenges of collaborative efforts and data sharing in TBI research. We also discuss a novel approach in which systematic reviews are continually updated to optimise existing evidence, and we review the potential for knowledge transfer to facilitate implementation of evidence into practice.

Comparative effectiveness research

Approaches to CER

CER is the generation and synthesis of evidence to compare the benefits and harms of different approaches to delivery of care, or of methods to prevent, diagnose, monitor, or treat a clinical condition. The purpose of CER is to assist consumers, clinicians, purchasers, and policy makers to make informed decisions that will improve health care at both the individual and the population levels.487 The applicability of research results to daily clinical practice is central to CER. Approaches to CER can include both experimental and non-experimental designs. Experimental designs include pragmatic RCTs, which, in contrast to traditional RCTs, use broad inclusion criteria to increase the generalisability of results while maintaining
the benefits of randomisation. Non-experimental designs are generally based on observational studies that exploit existing variability in care and outcome to compare systems of care or interventions. Non-experimental designs are methodologically challenging and there is a high risk of so-called confounding by indication—ie, finding an association between an intervention and an outcome in the absence of a causal connection since the selection of patients who receive the intervention is not random, but rather is influenced by patient characteristics, physician preferences, or other uncontrolled factors. Expert methodological input is required to deal with the potential problems of confounding by indication. Large-scale studies, based on collaborative efforts, that capture sufficient detail and are underpinned by careful design and analysis plans, are essential for robust CER outputs.

Application of CER to TBI
CER has particular potential in the field of TBI for several reasons. First, there are large between-centre and between-country differences in both management and outcome. Second, robust risk-adjustment models are available for TBI, allowing adjustment for patient and injury characteristics that might affect outcome. Third, advanced statistical models, including random effects models, are available to analyse differences between centres. Existing variability could relate to structural parameters (eg, level I vs level II trauma centres, or high-volume vs low-volume centres), or process parameters (eg, choice of surgical procedures, use of ICP monitoring, choice of acute management protocols, or choice of rehabilitation interventions).

In the IMPACT studies, data were analysed from 9578 patients with moderate or severe TBI from 265 centres, and a 3.3-times difference in the odds of unfavourable outcome was found at 6 months between centres at the two extremes of the outcome range (2.5th vs 96.75th percentiles). This difference persisted after adjustment for chance effects and differences in case-mix. Similarly, an analysis of 9987 patients across the TBI severity spectrum from 237 centres in 48 countries from the CRASH trial showed a 6.6-times difference in 14-day mortality between centres with the lowest (2.5th percentile) and highest (96.75th percentile) mortality rates after adjustment for chance and case-mix (appendix p 10). Both studies, however, had insufficiently detailed data to relate these outcome differences to differences in structure or process of care.

Many interventions that are part of current clinical practice are not readily assessed using RCTs. In many instances, this is because the uncertainties about the interventions involve complex protocols of management (such as the order in which aggressive therapies should be used for intracranial hypertension) rather than efficacy of individual treatments. In other instances, RCTs might be challenging owing to lack of clinical equipoise within individual centres where a given approach is strongly established, despite substantial heterogeneity in practice between centres (as is the case with surgery for contusions). CER approaches could provide a more cost-effective means of evaluating these interventions (and, potentially, novel therapies) in real-world settings. Early evidence in support of non-experimental designs as a promising approach for research on severe TBI comes from studies that relate outcomes to structural parameters (section 4) or that compare surgical or medical interventions (ie, process parameters) (section 5) using CER.

In guideline development, however, evidence from non-randomised clinical studies is regarded as inferior to that generated by RCTs. The recent update of the guidelines on management of severe TBI—which resulted in high-quality (level 1) recommendations for just one topic—illustrates the methodological rigour with which evidence is currently being evaluated. We suggest that evidence from high-quality non-randomised and observational studies could be as valuable as that from RCTs, since the increased generalisability of such studies provides specific practical benefits.

Collaborative approaches to accelerate TBI research
Since the 1970s, there has been a rich tradition of academic collaboration for advancement of TBI management. In the 1980s, the US National Traumatic Coma Data Bank provided important data on acute physiology and outcome, which underpins much of current clinical practice. This tradition continues in the USA, perhaps best exemplified by the TBI Model Systems Program, which provides valuable data based on everyday practice, particularly for postacute services, in collaborating US centres. More recently, US and Indian neurosurgeons formed a new coalition, The Indian Traumatic Brain Injury Consortium, and have implemented a pilot project in Andhra Pradesh, southern India, to improve outcomes after TBI by optimising systems of care and care pathways. Important outputs have resulted from international consortia (such as the CHIRAG [Collaborative Head Injury and Guidelines] study group and the European Brain Injury Consortium), clinical trials consortia (such as the Australian and New Zealand Intensive Care Society Clinical Trials Group) and national audit programmes (the UK Intensive Care National Audit and Research Centre). More recent initiatives include the TBI Endpoints Development project and the Chronic Effects of Neurotrauma Consortium, which addresses the late effects of TBI. However, the past few years have seen a more strategic approach to the encouragement of such collaboration, which represents synergistic efforts not only of researchers, but also of national and international funding agencies.

International Initiative for TBI Research
The need for a reappraisal of research design and implementation of broad-based, sustainable multidisciplinary and international approaches was recognised...
in 2010 by major funding agencies. This led to the establishment of the InTBIR, which represents a concerted effort to tackle the vast global health problem posed by TBI. The InTBIR initially arose as a collaboration between the European Commission, the US NIH–National Institute of Neurological Disorders and Stroke, and the Canadian Institute of Health Research, and was more recently joined by One Mind (a non-governmental organisation) and by the US Department of Defense. Table 3 summarises the initial studies supported within the InTBIR collaboration, which cover the entire spectrum of TBI. Each has a different focus but a common goal: to better understand TBI, and to improve its prevention, treatment, and outcomes.

The InTBIR studies will include over 40,000 patients with TBI of all severities, many of whom will provide novel genomics, biomarker, and advanced imaging data. The outputs are expected to provide a rational basis for optimisation of health-care delivery for populations and clinical management for individual patients (figure 14). Additionally, these studies will establish well curated biorepositories and databases, which will provide a legacy for future research on blood samples from well characterised populations of patients with TBI as new methods are developed or longer follow-up becomes possible. All projects comply with standards based on the Common Data Elements, which allow clinical investigators systematically to collect, analyse, and share data across the research community. European and Canadian studies will address the internationalisation of these Common Data Elements, allowing a US-based process to be applied globally, and promote global data standards for TBI research. This harmonised data collection will permit meta-analyses of data from large numbers of patients—essential for CER and improvement of TBI characterisation—and deliver outputs that would be impossible with any individual study.

This collaboration of international funding agencies is unique. The total overall funding for the InTBIR studies listed in table 3 will be approximately US$90 million between 2012 and 2020, which represents an enormous increase from past levels of funding for TBI research, but this is still disproportionately low when compared with that for other neurological diseases. An estimate based on figures from the International Alzheimer’s Disease Research Portfolio suggests that global funding for research into dementia, a disease with a comparable impact to TBI, was US$3.4 billion between 2008 and 2014. Furthermore, between 1998 and 2008, an estimated US$432 million was spent globally on research into frontotemporal dementia, a condition with a global incidence of 2.7–4.1 per 100,000 people per year. Given the vastly greater number of patients with TBI and the huge cost burden worldwide, substantial increases are warranted in funding to support neurotrauma research.

Towards global collaborations

The concept of large-scale observational studies combined with CER, as implemented in the InTBIR initiative, has attracted global interest and resulted in a number of linked collaborative projects. In China, a large-scale observational study was initiated in August 2015 and recruitment was completed in June 2017. In total, 13,583 patients with TBI were included from 61 sites (Gao G, unpublished). In India, an observational study named CINTER-TBI (Comparative Indian Neurotrauma Effectiveness Research-TBI) was initiated in June 2016 and recruitment was recently expanded to six centres (Gupta D, unpublished). The involvement of China and India, with their large populations and dramatically increasing TBI burden, provides a platform for high-quality research in these countries. Both studies are autonomous and conducted nationally, and were investigator-driven with minimal or absent local funding. Data collection in both studies is harmonised with CENTER-TBI to enable meta-analyses across studies. Therefore, for the first time, data collection in the field of TBI is globally harmonised and coordinated.

In view of the trend for clinical trials initiated by pharmaceutical companies to be moved from Europe and the USA to east Asia, the international collaborations described above could deliver key insights into the generalisability of results. These initiatives reflect increasing recognition of the potential benefits of broad collaborations and represent a new approach to research, to which funding agencies must adapt to enable truly global collaborations. Major challenges include a lack of funding mechanisms for global research and restrictions to crossborder data transfer owing to privacy legislation. Despite the collaborative ethos of the InTBIR initiative, the studies conducted under its aegis are funded independently by respective funding agencies, and funding is not currently planned for meta-analyses across InTBIR studies, or with linked projects such as the initiatives in China and India. The greatest synergies will emerge from integrated analyses of the combined data in all relevant studies. The initiative established by the InTBIR needs to be expanded globally, and consolidated by facilitating meta-analysis across studies, thus ensuring future research continuity.

Data sharing

CER and precision-medicine research in TBI require large sample sizes and data sharing. Funding bodies, journal editors, and research regulators promote such sharing. Although the principle of data sharing receives almost universal support, implementation is not easy. Any solution must comply with privacy and ethical regulations, ensure high-quality data standards, promote sensible data use, maintain incentives for researchers who collect data, and appropriately account for the true costs of data sharing. Balancing these competing demands is challenging.
Consent issues
In TBI, particular challenges arise from loss of capacity to consent and from the need to initiate data collection as early as possible after injury. In the USA, the Health Insurance Portability and Accountability Act regulations\(^5\) recognise proxy consent in principle, and permit the use of a waiver of consent, particularly if underpinned by community consultation. The regulatory situation in EU jurisdictions is in a state of flux: the General Data Protection Regulation (regulation 2016/679) will apply from May 2018,\(^6\) and although it makes provisions for research, it remains ambiguous with regard to incapacitated patients in emergency situations. There is a strong case for explicitly defining the acceptable use of data for legitimate clinical research in this context, and doing so in a way that meets the research needs of TBI and other acute diseases that could be characterised by lack of capacity to consent.

Intellectual capital and costs of data sharing
The emergence of open data sharing has created clear tensions with the way in which research success is currently measured. Given that the conventional currency...

(Continued from previous page)
data-mining tools could allow identification of individuals in supposedly anonymised datasets. One possible solution could be provided by so-called gatekeeper software, which balances the seemingly irreconcilable demands of access versus privacy through differential privacy algorithms. However, technology can provide solutions only in the context of rational regulation, and any digital solutions will need to be underpinned by new paradigms of consent and social contracts between researchers and patients. Emerging trends provide cause for optimism in this context.

Optimising existing evidence: living systematic reviews

Health-care decisions should be informed by knowledge about what works and what does not. Such understanding is best achieved with systematic reviews that assess and critically appraise integrated results from multiple studies using transparent and reproducible methods. However, conventional systematic review processes are labour-intensive and time-consuming, often undertaken by small teams working in isolation, and seldom updated as new research is published. In an analysis of 792 studies incorporated into 73 systematic reviews across 28 neurotrauma topics, the median time from primary study publication to its inclusion in a published systematic review ranged from 2.5 to 6.5 years. Therefore, systematic reviews are often outdated by the time they are published.

An innovative knowledge-management approach known as living systematic reviews (LSRs) is currently being pioneered within the CENTER-TBI project. LSRs are timely and high-quality online summaries of health research that are updated as new studies become available. LSRs transform the production of systematic reviews from a process of undertaking sporadic large projects every few years to an activity characterised by ongoing surveillance and more frequent smaller packages of work as new research findings emerge. Whereas the main questions driving conventional reviews relate to the totality of evidence and what it tells us about the effectiveness of an intervention or the accuracy of a diagnostic test, for example, the real-time nature of LSRs shifts the emphasis to the question of how the new evidence changes what we already know.

By pairing clinical TBI experts with experts in systematic review methods, the teams leading the InTBIR studies are laying the foundations for an ongoing dynamic TBI knowledge base and community. To date, two LSRs have been published, and topics planned for future LSRs cover diagnosis, prognosis, and interventions. Completed reviews are published in an open-access format. Searches are being automatically run every 3 months, and machine-learning technology is being piloted to reduce the workload. LSRs are a new challenge for academic publishers, but the Journal of Neurotrauma has agreed to include updates in the online versions of reviews at approximately 3–6 month intervals.

The LSR author groups will also seek to publish updates as new manuscripts—subject to peer review—when new evidence leads to a change in conclusions.

Interest in LSRs is growing rapidly, with multinational research collaborations being formed to maintain and curate the evidence base in a range of clinical areas. Notably, Cochrane, the global producer of systematic reviews, is also piloting LSRs. In the field of TBI, these pioneering efforts of CENTER-TBI are now being integrated within the InTBIR initiative. However, funding is limited to the duration of current InTBIR studies. We need mechanisms to ensure future continuity, in terms of both knowledge management and funding.

One of the most attractive aspects of a living evidence synthesis model is the potential to produce living clinical practice guidelines or recommendations, and this is currently being considered by the Brain Trauma Foundation, the main producer of guidelines in TBI. While we strongly support a move towards living guidelines, an alternative approach could be to consider LSRs as the evidence base upon which more practical treatment recommendations can be tailored to national and local settings. A major criticism of current guidelines is that the emphasis on methodological rigour has decreased their practical value. Presenting the evidence base and practice recommendations separately might be

---

**Figure 14: Aims of the International Initiative for Traumatic Brain Injury Research**

The International Initiative for Traumatic Brain Injury Research (InTBIR) studies will involve collection of a range of clinical data, biosamples, and longitudinal outcome data in observational studies and pragmatic trials, creating a highly detailed information commons (the body of evidence on traumatic brain injury [TBI]). The aims of these studies are to improve understanding of the causes and mechanisms of TBI to inform prevention strategies (prevention) and of disease characterisation to facilitate diagnosis and targeted treatment (precision medicine). Data from comparative effectiveness research (CER) will be analysed with the aims of identifying the most effective and targeted therapies (best practice) and translating them into practice recommendations. The increased data on patient and injury characteristics should improve prognostic accuracy, which in turn could enable improved benchmarking of care (quality of care).

For the Federal Interagency Traumatic Brain Injury Research informatics system see https://fitbir.nih.gov/
a way to combine methodological rigour with practical applicability. There is also a growing recognition of the value of practice recommendations based on expert consensus to facilitate care delivery for areas of clinical practice for which rigorous guidance is lacking or unclear.41 While ongoing efforts continue to strengthen the evidence base, ensuring the practical relevance of guidelines is essential to stimulate their implementation into clinical practice.

Implementing evidence into practice: knowledge translation
Translating evidence into practice and policy has become a distinct science, which complements that of discovering, developing, and synthesising research results. The emerging field of knowledge translation is defined as “the science of developing strategies to integrate evidence-based knowledge into health policy and practice, based upon understanding of behavioural drivers of practice within specific settings”.30 The science of knowledge translation has developed in response to recognition of gaps between research evidence and clinical practice. The evidence-based practice movement of the early 1990s34 reshaped clinical practice by promoting consideration of best evidence, clinical expertise, and patient preferences in making treatment decisions.143 Nevertheless, a series of landmark studies published in the early 2000s revealed that only 55–67% of patients received recommended care, and 20–25% received care that was unnecessary or potentially harmful.345 In the field of TBI, a recent systematic review247 concluded that although guideline adherence was associated with improved outcomes, general adherence to guidelines was highly variable, and in many instances, poor. For example, the mean figure for adherence to the Brain Trauma Foundation guidelines for ICP management was 31% (range 18–83%).267 There is much to be gained from harnessing knowledge translation to address the evidence–practice gap in TBI.

Economic modelling has shown that more widespread adoption of Brain Trauma Foundation guidelines across the USA could save more than 3500 lives, and, by raising the proportion of favourable outcomes from 35% to 66%, could yield an estimated annual cost saving of US$4 billion.248

Use of a knowledge-translation approach involves three core tasks: defining the target behaviour, measuring current behaviour, and understanding current behaviour. Defining the target behaviour establishes the desired health-care standard by which the success of a knowledge-translation intervention can be measured. For example, the Brain Trauma Foundation guidelines on nutrition after TBI recommend “feeding patients to attain basal caloric replacement at least by the fifth day and, at most, by the seventh day post-injury” to decrease mortality.294

Next, knowledge of current practice is required to determine the scope and nature of the evidence–practice gap.245351351 Hart and colleagues527 examined adherence to the guideline on nutrition and found that patients not fed within 5 and 7 days after TBI had a 2-times and 4-times increased risk of death, respectively, and that every 10-kcal/kg decrease in caloric intake was associated with a 30–40% increase in mortality rate.527 These data underscore the importance of ensuring that practice reflects evidence.

Finally, understanding behaviour is necessary for successful implementation of new practices. Quantifying the evidence–practice gap defines the problem but does not give information on why practice is the way it is. Gaining this understanding of behaviour before attempting a quality-improvement (knowledge-translation) strategy is essential; without such understanding, precious resources can be wasted. For example, a common assumption is that people do not follow guidelines because they are not aware of them. This frequently drives educationally focused strategies such as lecture presentations and passive guideline dissemination. However, there are numerous barriers to best practice other than lack of knowledge, including peer-group influence, attitudes and beliefs of health professionals, organisational barriers such as lack of equipment, and structural barriers such as financial disincentives (panel 14).30 By addressing only the assumed barrier of lack of awareness, an educational quality-improvement strategy risks being ineffective and wasting resources.

We invite the reader to engage in frank introspection, considering the range of barriers to evidence-based, guideline-driven care, and challenge decision makers and clinicians to develop a plan of attack to guide implementation of evidence into practice. Every hospital that seeks to implement TBI guidelines will need to run its own thought experiment, because the barriers are likely to vary by location. Planning holds the promise of avoiding traditional pitfalls if sufficient resources can be brought to bear on the question of not just what to implement, but also how to implement evidence into practice.
practice. It is important that all stakeholders recognise the need for funding and resources to support knowledge transfer in TBI—a vital step in bridging the gap between evidence and practice. For more on this thought experiment, see appendix p 11.

Advances in both the science and the uptake of knowledge translation are required to close the evidence–practice gap. A key challenge for knowledge-translation scientists is the existence of multiple terms (eg, “dissemination and implementation research”, “quality improvement”, “implementation science”, and “research translation”) and frameworks to understand, describe, and influence the behaviour of health-care practitioners. Knowledge-translation scientists are working to address this challenge through the development of conceptually simpler and shorter frameworks that can be used to standardise knowledge-translation interventions in a similar way to the standardisation achieved in the clinical trials arena with the Consolidated Standards of Reporting Trials (CONSORT) statement. One such example is the AIMD framework, which seeks to characterise knowledge-translation interventions in terms of four domains identified as integral to all such interventions: Aims (purpose and target of behaviour change), Ingredients (what makes up the intervention), Mechanism (how the intervention is proposed to work on the basis of behavioural theory), and Delivery (mode of delivery—eg, online or printed material). Uptake of knowledge-translation science needs to be increased in clinical and other communities that are less familiar with applying behavioural theory to close the evidence–practice gap. It is hoped that clinician engagement in universal and simple frameworks can contribute to this.

Health-care quality improvement is complex and there is never likely to be a one-size-fits-all approach. What is beyond dispute, however, are the words of the former Director General of WHO, Lee Jong-wook: “Health work teaches us with great rigour that action without knowledge is wasted effort, and knowledge without action is a wasted resource.”

Key messages and recommendations

Key messages

(1) Substantial between-centre variability in treatment and outcome in TBI offers unique opportunities for CER to improve the strength of clinical evidence.

(2) Funding mechanisms for global research efforts in TBI are inadequate and poorly integrated, limiting efforts to tackle the growing public health problem posed by TBI.

(3) Standardisation of clinical data collection, based on the TBI Common Data Elements, provides a common language for global research.

(4) CER studies and research on disease characterisation, outcome, and prognosis will require many patients, large datasets, and broad data sharing.

(5) Collaborations formalised in data-use agreements offer the best guarantee for driving research and care forward, but existing frameworks for recognising the success of research projects, individual researchers, or institutions are a major obstacle to data sharing.

(6) TBI is often characterised by incapacity of patients to provide informed consent for participation in research.

(7) Overly restrictive interpretation of privacy legislation can inhibit or even prevent research and data sharing in TBI and other conditions that result in loss of capacity to consent.

(8) There are substantial delays in integrating research results into recommendations for best clinical practice.

(9) In TBI, as in many areas of medicine, substantial gaps exist between best current evidence and clinical practice. Barriers to transfer of knowledge from research to the clinic include lack of dissemination or awareness, inflexible attitudes, erroneous beliefs, and organisational and structural barriers. Such barriers can result in poorer patient outcomes.

Recommendations

(1) CER should be supported to identify best practices and to improve the level of evidence for systems of care and diagnostic and therapeutic interventions.

(2) A commitment of governmental and non-governmental funding bodies, as well as industrial partners, is needed to foster global collaborations and to establish national and international biorepositories and databases that could facilitate future TBI research.

(3) The Common Data Elements need to be made internationally applicable to ensure global standardisation of clinical data collection.

(4) Investment is needed in systems for efficient collection and sharing of data across borders, including funding of costs for rigorous data curation, annotation, and long-term database maintenance to maximise the returns on research investment from public funding.

(5) The current way in which research is valued needs to be critically assessed and revised, and funders should provide incentives for data collection and sharing.

(6) Regulatory frameworks for research should take account of acute loss of capacity to give consent in conditions such as TBI, and include appropriate provisions, such as recognition of waived, deferred, or proxy consent, to allow vital research to continue.

(7) Regulation should avoid unnecessarily restrictive interpretation of privacy clauses and complex bureaucratic procedures to enable greatly needed research and productive data sharing.

(8) Funders and publishers should support rapid transfer of new research results into the evidence base, facilitated by new digital tools for their subsequent collation and integration into LSRs. LSRs should form the basis for practical treatment recommendations, with potential for a transition towards living clinical guidelines.

(9) Information campaigns, resources, and strategies to change clinicians’ behaviour are essential to overcome barriers to knowledge translation, and to ensure
implementation of guidelines and best practice to optimise the benefits of future research advances in clinical practice, improve outcomes, and make cost savings in health care.

Conclusions
TBI is likely to remain the largest global contributor to neurological disability until the end of the next decade, with a predicted burden of disability that far exceeds that of conditions such as cerebrovascular disease and dementia.5 Crucially, TBI-associated disability often affects young people at their productive peak, and results in huge burdens to individuals, families, and society (section 1). Extrapolation from available estimates suggests a global annual cost of TBI as high as US$400 billion—a figure that represents approximately 0.5% of gross world product (section 2). The precise magnitude of the problem, however, remains largely uncharted. Current estimates of 50–60 million new TBIs per year globally are an approximation because wide variations in methodology exist between countries, including differences in data capture and reporting. We urgently need consensus on descriptors of TBI and its severity, as well as standardisation of methods for epidemiological monitoring across countries. Worldwide, patterns of TBI are changing, with increases in road traffic injuries in LMICs and a growing problem with falls among elderly individuals in HICs. Other key drivers that contribute to the burden of TBI include sports-related concussion and international conflict. Regardless of the cause, TBI results in an enduring burden of late morbidity and increased mortality, and might represent a risk factor for dementia in later life;29 the attributable risk from TBI to overall dementia incidence could be as high as 5–15%.100 Improved knowledge of epidemiology will be key to more effective targeting of TBI prevention strategies in different populations (section 3).

When TBI does occur, we need better ways to organise systems of care that provide cost-effective approaches to minimise preventable mortality and morbidity, ensuring that patients receive appropriate health care as soon as possible (section 4). Substantial variations in outcome exist between centres, and tackling these differences has the potential to far outweigh any benefit that might be realistically expected from a new treatment. There is growing evidence of a relation between management in high-volume centres and improved outcomes,29–23 which suggests that care for the most critically ill patients should be centralised. Substantial gains could be made from provision of adequate prehospital care, appropriate referral, and continuity along the chain of care, with early access to effective rehabilitation. The solutions that relate to care systems for TBI must take account of local economic and social factors and, in particular, work is needed to develop cost-effective systems of care in LMICs.

Clinical management of TBI should be based on robust guidelines. However, evidence in support of guideline recommendations is often weak and not applicable to all patients, as most studies that contribute to guideline development are population based and do not take into account the heterogeneity of TBI type and severity, or differences in individual patient characteristics. As a result, current management strategies are based on guidelines that favour a one-size-fits-all approach, and the care of patients with TBI is therefore poorly individualised (section 5). Moreover, despite investment of many billions of dollars by pharmaceutical companies, no effective drugs exist for treatment in the acute setting—a failing due, in part, to insufficient targeting of therapies to patients in whom the relevant mechanism is active. We need better methods to characterise TBI to allow identification of patient subgroups with a common dominant disease mechanism, who are more likely to respond to specific treatments—a concept now being popularised as precision medicine (section 6). We also need to enable better characterisation of outcome after TBI: mortality is an inappropriate metric for a disease that can result in considerable disability in survivors, and current outcome assessment tools are limited by their unidimensional approaches. We need improved multidimensional outcome assessment schemes that take better account of the substantial physical, cognitive, behavioural, and mental health sequelae of TBI (section 7). Improved disease and outcome characterisation will also provide a robust foundation for better prognostication of outcome. This could support better counselling of patients and relatives, help in management planning for individual patients, improve comparative audit of care between centres and countries, and facilitate research (section 8). Huge opportunities exist for improvements in characterisation of initial severity, outcome, and prognosis, and for more accurate tracking of disease processes, by building on the current scientific advances in modern neuroimaging, genomics, disease biomarker development, and pathophysiological monitoring. Developments in these technologies could facilitate the goals of precision medicine in TBI.

CER is a novel approach in which disease heterogeneity—in terms of clinical and pathophysiological type and outcome—and variations in clinical management and systems of care can be exploited to identify best practices (section 9). The data gathered from such research in real-world situations could enrich the limited evidence base on clinical care for TBI. Critical gaps in our knowledge of how best to treat TBI necessitate common standards for imaging and laboratory results, so
that outputs from different studies can be usefully integrated. In the past, industry has been a valuable partner in promoting networking and supporting research endeavours, thus contributing to improved TBI care. We need to continue to facilitate such support through regulatory design and collaborative funding arrangements.

Large cohorts of patients are needed for research to deliver meaningful advances in precision medicine, for robust CER, and to improve prognostic schemes. Such studies can be realised only through global collaboration (section 9). Current international initiatives, such as the InTBIR initiative, and a growing ethos of data sharing represent an unprecedented opportunity to achieve these aims. However, such collaborative approaches to research depend on regulatory frameworks that enable consent for research and data sharing—a growing concern in the context of ever more rigorous privacy legislation, particularly in the context of TBI, in which patients often lose the capacity to consent at the onset of injury. Regulatory frameworks need to provide ways to legitimise research in the context of TBI and other conditions in which explicit patient consent cannot be obtained, and to implement solutions that resolve the conflict between personal privacy and wide access to research data. Research funders also need to recognise the substantial costs of data sharing.

The knowledge that is gained from clinical research must be rapidly translated to improvements in care. However, the gap between study publication and integration of results into a systematic review can be as much as 6–5 years, with a further delay before such integrated information is translated into clinical guidelines. Novel digital tools for literature searching and integration could speed up this process with the development of LSRs and living guidelines, which are continually updated as new information becomes available.

The problems and potential solutions described in this Commission have been inspired by patients and brought together by a wide international group of active clinical researchers who seek to improve outcomes for people with TBI. Clinicians and researchers, in consultation with patients and their families, need to play their part in taking these recommendations forward. Collaboration between funding agencies will be required to coordinate the strategy and conduct of research, and commitment from policy makers will be essential to facilitate research and ensure timely implementation of research outputs. Implementation of prevention strategies and provision of optimum clinical care in different settings should be a priority for clinicians and policy makers alike. Integration of all these efforts should deliver rich dividends in terms of better and more cost-effective care, with huge benefits for patients, their families, and society as a whole.

Contributors
AIRM and DKM led the Lancet Neurology Commission on traumatic brain injury, oversaw the collation of sections, and performed the final general editing of the manuscript. They contributed equally. The main authors provided draft text and contributed to (parts of) the various sections, as follows. AIRM and DKM wrote the introduction. Patient testimonies were provided by L-E L and JP. Authors for section 1 included VLF, M Maaj, WS, EWS, and AT, with input for subsections from PDA, MJ B, ABE, ABr, ATC, RD-A, ACD, GG, DG, JyJ, TER, BTA, and WHW. Authors for section 2 included SP and BTA. Authors for section 3 included MJ B, PDA, FL, M Maaj, NS, and DT. Authors for section 4 included NA, MCo, GG, JyJ, FL, SP, and RR. Authors for section 5 included NA, GC, RMC, TAE, JG, GM, WP, NS, OT, WV, and KY. Authors for section 6 included AE, SH, GM, CMCF, SM, VN, PMP, WS, and KKWW, with input for subsections from ABi, MCz, DJC, EC, JPD, JAN, NK, SL, MAAE, LM, AP, LP, PS, SJS, DT, and KY. Authors for section 7 included NA, JH, MBS, NV, OT, and IW. Authors for section 8 included HFL and EWS. Authors for section 9 included PB, TWE, RLG, SH, EJO, HL, HFL, GM, JM, JS, and AS. The group authors—more than 250 contributors designated as the International Initiative for Traumatic Brain Injury Research (InTBIR) Participants and Investigators, listed at the end of the paper—contributed by means of online simultaneous editing of the manuscript, with all changes tracked and visible to all contributors. All authors had an opportunity to comment on and edit the first (January 2016) and second (March 2017) submissions. The final version of the manuscript was reviewed and approved by all main authors.

The Lancet Neurology Commission

Acknowledgments

We are extremely grateful to our patients with traumatic brain injury (TBI)—the Commission’s most important stakeholders—who have shared their experiences with us and taught us so much. In adopting a pioneering approach to the editing of this paper, including contributions from more than 250 International Initiative for Traumatic Brain Injury Research (InTBIR) Participants and Investigators, an important aim has been to recognize the efforts of investigators who collect data in large-scale observational studies and clinical trials, such as the InTBIR studies. Without their time and effort, no data or evidence base would exist to support progress in the field. We acknowledge the support provided by the funding agencies joined in the InTBIR initiative: the Canadian Institutes of Health Research, the European Commission, the US National Institutes of Health-National Institute of Neurological Disorders and Stroke, One Mind, and the US Department of Defense. Additional support for Canadian studies within InTBIR was provided by Fonds de recherche du Québec-Santé, the Hotchkiss Brain Institute, the Ontario Brain Institute, and the Ontario Neurotrauma Foundation. The Collaborative European NeuroTrauma Effectiveness Research in Traumatic Brain Injury (CENTER-TBI) project received additional support from the Hannelore Kohl Stiftung, Germany. Synergistic funding for the Transforming Research and Clinical Knowledge in Traumatic Brain Injury (TRACK-TBI) study was obtained through a successful application for a TBI Endpoints Development award from the US Department of Defense. In addition, DKM was supported through a Senior Investigator Award and funding for the Cambridge Biomedical Research Centre from the UK National Institute for Health Research. We thank Maartje Kunen for providing the images for figures 6 and 11. The preparation of this manuscript would not have been possible without the administrative and graphical support of Fanny Hermanns, Veronique de Keyser, and Onarda Tarrazi; we are very grateful for their help.
