Multivariate tests for patterned covariance matrices

Francesca Greselin, Salvatore Ingrassia and Antonio Punzo

Abstract In many real datasets, the same variables are measured on objects from different groups, and the covariance structure may vary from group to group. Often times, the underlying population covariance matrices are not identical, yet they still have a common basic structure, e.g. there exists some rotation that diagonalizes simultaneously all covariance matrices in the groups, or all covariances can be made congruent by some translation and/or dilation. The purpose of this paper is to show how a test of homoscedasticity can be made more informative by performing a separate check for equality between shapes and equality between orientations of the concentration ellipsoids. This approach, combined with parsimonious parametrization in mixture data modeling, provides a formal hypothesis testing procedure for model assessment.

Key words: Homoscedasticity, Spectral decomposition, Principal component analysis, F-G algorithm, Multiple tests, UI tests, IU tests.

1 Introduction and basic definitions

In multivariate analysis it is customary to employ an unbiased version of the likelihood ratio (LR) test to ascertain equality of the covariance matrices referred to several groups. However, in many applications, data groups escape from homoscedasticity; nevertheless, one can observe some sort of common basic structure among covariance matrices, i.e. they share orientation or shape or size. To this aim, their spectral decomposition is employed, i.e. the eigenvalues and eigenvectors representation, as suggested by many authors in the literature, see [?]). In clustering males and females blue crabs [?] by a mixture model-based approach, Peel and McLachlan [?] assumed that the two group-conditional distributions were bivariate normal with...
common covariance matrix, on the basis of Hawkins’ test. As pointed out by the authors, this assumption produced a larger misallocation rate than the unconstrained model. Greselin and Ingrassia in [?] resolved this apparent contradiction, requiring only covariances matrices with the same set of (ordered) eigenvalues, i.e. ellipsoids of equal concentration with the same size and shape. In the present paper, Flury’s proposal and the above remarks on patterned covariance matrices are jointly considered to provide a unified framework for a more informative scedasticity comparison among groups.

Now we introduce some basic notation and definition: supposing to deal with \( p \) variables measured on objects arising from \( k \geq 2 \) groups, let \( x_{1}^{(h)}, \ldots, x_{n_{h}}^{(h)} \) denote \( n_{h} \) independent observations, for the \( h \)-th group, drawn from a normal distribution with mean vector \( \mu_{h} \) and covariance matrix \( \Sigma_{h}, \ h = 1, \ldots, k \). Let \( \Sigma_{h} = \Gamma_{h} \Lambda_{h} \Gamma_{h}^{\prime} \) be the spectral decomposition of \( \Sigma_{h} \), where \( \Lambda_{h} = \text{diag}(\lambda_{1}^{(h)}, \ldots, \lambda_{p}^{(h)}) \) is the diagonal matrix of the eigenvalues of \( \Sigma_{h} \) sorted in non-increasing order and \( \Gamma_{h} \) is the \( p \times p \) orthogonal matrix whose columns are the normalized eigenvectors of \( \Sigma_{h} \) ordered according to their eigenvalues, \( h = 1, \ldots, k \); here, and in what follows, the prime denotes the transpose of a matrix. On the other hand, \( k \) covariance matrices which share the same matrix of orthonormalized eigenvectors \( \Gamma_{1} = \cdots = \Gamma_{k} = \Gamma \) have ellipsoids of equal concentration with the same axis orientation in \( p \)-space, i.e. they are congruent up to a suitable dilation/contraction (alteration in size) and/or “deformation” (alteration in shape). By using the Greek term “\( \iota \rho \o \pi \sigma \)os” (orientation), we call it “homotroposcedasticity”.

When homometroscedasticity and homotroposcedasticity simultaneously hold, we have homoscedastic data. Moreover, an intermediate situation between heteroscedasticity and homoscedasticity, denoted as “weak homoscedasticity” can be devised, when only one of the two above conditions holds.

2 More informative multiple tests to compare “scedasticity”

Consider the null hypothesis of homometroscedasticity \( H_{0}^{\Lambda} : \Lambda_{1} = \cdots = \Lambda_{k} = \Lambda \) versus the alternative \( H_{l}^{\Lambda} : \Lambda_{l} \neq \Lambda_{1} \) for some \( h, l \in \{1, \ldots, k\}, h \neq l \). \( H_{0}^{\Gamma} : \Gamma_{1} = \cdots = \Gamma_{k} = \Gamma \) versus the alternative \( H_{l}^{\Gamma} : \Gamma_{l} \neq \Gamma_{1} \) for some \( h, l \in \{1, \ldots, k\}, h \neq l \).

A test of homoscedasticity can be re-expressed by a union-intersection (UI) test as \( H_{0}^{\Lambda} : H_{0}^{\Lambda} \cap H_{0}^{\Gamma} \) versus \( H_{1}^{\Lambda} : H_{1}^{\Lambda} \cup H_{1}^{\Gamma} \). Differently from a usual test of homoscedasticity, the present approach shows its profitability whenever the null hypothesis \( H_{0}^{\Lambda} \) is rejected: the component tests for \( H_{0}^{\Lambda} \) and \( H_{0}^{\Gamma} \) can discriminate the nature of the departure from \( H_{0}^{\Lambda} \). On the other hand, a test of weak homoscedasticity may be formulated as an intersection-union (IU) test: \( H_{0}^{\Lambda} : H_{0}^{\Lambda} \cup H_{0}^{\Gamma} \) versus \( H_{1}^{\Lambda} : H_{1}^{\Lambda} \cap H_{1}^{\Gamma} \).

Testing homometroscedasticity. Let \( \bar{x}_{h} \) and \( S_{h} \) respectively be the sample mean vector and the unbiased sample covariance matrix in the \( h \)-th group, \( h = 1, \ldots, k \). Moreover, let \( G_{h} \) be the \( p \times p \) orthogonal matrix whose columns are the normalized eigenvectors of \( S_{h} \) ordered by the non-increasing sequence of the eigenval-
ues of $S_h$, $h = 1, \ldots, k$. According to the principal component (linear) transformation $x_i^{(h)} \rightarrow y_i^{(h)} = G_h^i (x_i^{(h)} - \bar{x}_h)$, $i = 1, \ldots, n_h$, the data $y_1^{(h)}, \ldots, y_{n_h}^{(h)}$, are uncorrelated, and their covariance matrix $L_h$ is the diagonal matrix containing the non-negative eigenvalues of $S_h$. Since the assumption of multivariate normality holds, these components are also independent and normally distributed. Based on these results, the null hypothesis $H_0^h$ can be re-expressed as follows $H_0^h : \Gamma_h^y = \Lambda_h, h = 1, \ldots, k$.

To the best of the authors’ knowledge, a direct method to deal with the latter expression for $H_0^h$ does not exist. However, under the assumption of multivariate normality, Flury derived the log-LR statistics for testing the weaker null hypothesis $H_0^{\text{CPC}} : \Gamma_h^y \Sigma_h \Gamma_h = \Lambda_h, h = 1, \ldots, k$, where $\Gamma_h$ is a $p \times p$ orthonormalized matrix that diagonalizes all covariance matrices, and $\Lambda_h$ is one of the possible $p!$ diagonal matrices of eigenvalues in the $h$th group, $h = 1, \ldots, k$. Under $H_0^{\text{CPC}}$, no canonical ordering of the columns of $\Gamma_h$ is specified here. In order to apply Flury’s proposal, the $F$-$G$ algorithm can estimate the sample counterpart $G$ of $\Gamma$. Under $H_0^{\text{CPC}}$, the following transformation $x_i^{(h)} \rightarrow \tilde{y}_i^{(h)} = G_h (x_i^{(h)} - \bar{x}_h)$ holds, where the data $\tilde{y}_1^{(h)}, \ldots, \tilde{y}_{n_h}^{(h)}$ are uncorrelated with diagonal covariance matrix $L_h$ (the sample counterpart of $\Lambda_h$), for $h = 1, \ldots, k$. From a geometrical point of view, under $H_0^{\text{CPC}}$, the $k$ ellipsoids of equal concentration have the same orientation in $p$-space while, under $H_0^{\text{CPC}}$, they have only the same principal axes. For Hence, to test $H_0^{\text{CPC}}$, first we perform Flury’s test $H_0^{\text{CPC}}$ of equality between principal axes; afterwards, if $H_0^{\text{CPC}}$ is accepted, perform a statistical test to evaluate $H_0^h$. For further details about the tests, see [7]. Finally we remark that in order to preserve the chosen level $\alpha$ for the overall null hypothesis, the significance levels in the individual tests have to be devised with some care. In any case, the implemented R routine requires only the overall significance level and derives the component ones.

### 3 An application to clustering

In mixture-model based clustering, the conceptual analysis on similarities between covariance matrices allows a more parsimonious parametrization, and the scedasticity tests can be employed for model assessment. The following example illustrates the real gain in using these multiple tests combining them to parsimonious parametrization in mixture-modeling.
Table ?? shows the results obtained by applying the Mclust procedures, followed by the normality and scedasticity tests on the obtained clusters on the Crab dataset. The package suggests three best models, but they significantly differ in covariance structure and/or number of groups. For $k = 2$, a homometroscedastic (EEV) and a heteroscedastic (VVV) model are proposed; further, the slight difference of 0.983% in BIC values is of little help for the choice. Now, considering the first model and performing Mardia’s test on each cluster, the hypothesis of normality is accepted in both groups, while Box’s test fails, the new tests assess equality of the eigenvalues and reject equality of the eigenvectors in the two groups. In the second model, even if normality holds in each cluster and the test for homoscedasticity fails (as we expected, for a VVV model), the homometroscedasticity test on the two clusters assesses that they have the same eigenvalues. This contradiction leads to discard the second model. With reference to the third model, Mardia’s test rejects the null hypothesis of normality in one out of three groups and this allow us to discard the model. Hence the testing methodology selects the first model out of the three proposed by Mclust. As the true classification on the Crab is known, we can verify also that the first model has a significantly lower misclassification error, showing the real gain achieved by the testing methodology.
